
Provincial Infectious Diseases Advisory Committee
(PIDAC)

Ontario Agency for Health Protection and Promotion
Published: June 2008
Second revision: October 2011
The Ontario Agency for Health Protection and Promotion (now operating as Public Health Ontario) is an arm's-length government agency dedicated to protecting and promoting the health of all Ontarians and reducing inequities in health. As a hub organization, Public Health Ontario links public health practitioners, front-line health workers and researchers to the best scientific intelligence and knowledge from around the world. Public Health Ontario provides expert scientific and technical support relating to infection prevention and control; surveillance and epidemiology; immunization, health promotion, chronic disease and injury prevention; environmental and occupational health; health emergency preparedness; and public health laboratory services to support health providers, the public health system and partner ministries in making informed decisions and taking informed action to improve the health and security of Ontarians.

The Provincial Infectious Diseases Advisory Committee on Surveillance (PIDAC-Surveillance) was established to advise Public Health Ontario on the surveillance of infectious diseases and other microorganisms of epidemiologic significance to the health of Ontarians. The committee draws on the dedication of health care practitioners with expertise in infectious disease, infection prevention and control, epidemiology and public health.

DISCLAIMER FOR BEST PRACTICE DOCUMENTS

This document was developed by the Provincial Infectious Diseases Advisory Committee on Surveillance. PIDAC -Surveillance is a multidisciplinary scientific advisory body that provides evidence-based advice to Public Health Ontario regarding multiple aspects of infectious disease identification, prevention and control. The work of PIDAC-Surveillance is guided by the best available evidence and updated as required. Best practice documents and tools produced by PIDAC-Surveillance reflect consensus positions on what the committee deems prudent practice and are made available as a resource to public health and health care providers.

SUGGESTED CITATION

NOTES

This document is intended to provide best practices only. Health care settings are encouraged to work towards these best practices in an effort to improve quality of care.

Executive Summary

This document provides hospitals and long-term care homes with recommended best practices for the establishment of a surveillance system to detect health care-associated infections (HAIs) within their facility.

What is Surveillance?

Surveillance is the systematic, ongoing collection, collation and analysis of data with timely dissemination of information to those who require it in order to take action. The actions usually relate to improvements in prevention or control of the condition. Surveillance for health care-associated infections is normally performed by trained infection prevention and control professionals or hospital epidemiologists.

Why do Surveillance?

Health care-associated infections are an important and growing hospital and public health concern in Canada. The prevalence of both antibiotic-resistant organisms and of a vulnerable, immunocompromised population are increasing in hospitals and long-term care homes. There is conclusive evidence to show that the establishment of a surveillance system for HAIs is associated with reductions in infection rates. Surveillance is also useful in monitoring the effectiveness of preventive and infection control programs and is required for patient safety and mandatory reporting requirements in Ontario.

How is Surveillance Performed?

There are several established components to an active, effective surveillance system:

- Planning
  Because it is not feasible to monitor all types of infections at all times, choosing which infections will be surveyed is based upon an initial assessment that will establish the priorities for the surveillance system. An initial assessment will include:
  - the types of patients/residents that are served by the health care setting;
  - the key medical interventions and procedures that are provided in the health care setting;
  - the frequency of particular types of infections within a particular health care setting;
  - the impact of the infection (including per cent case fatality and excess costs associated with the infection); and
  - the preventability of the infection.

  Surveillance for some types of infections and syndromes, such as acute respiratory infection (ARI) and gastrointestinal (GI) illness, are currently part of routine practice in all health care settings.
Data Collection
Collection of infection data for surveillance purposes must be done using validated, published definitions for HAIs. If the definitions that are used to categorize an infection are not standardized, a health care setting’s infection rates cannot be accurately compared to either their own historical infection rates or to external benchmarks.

In order to generate valid HAI rates, information must be collected on those who are at risk of infection and whether or not they get ill. Electronic screening of patient records is an emerging tool for identification of potential HAIs. These computerized systems of case finding will reduce the time spent by Infection Control Professionals (ICPs) in case finding.

Long-term care homes will have a more limited range of information available for case finding, relying on ongoing contact and feedback from those directly involved in resident care.

Post-discharge surveillance for surgical site infection is becoming an increasingly important component of a surveillance system in acute care, due to shorter hospital stays following surgeries and an increasing proportion of surgeries taking place in the outpatient setting. Innovative strategies that do not put undue burden on their program resources are encouraged in hospitals to detect surgical site infections.

Data Analysis
It is recommended that incidence density rates be calculated in hospitals and long-term care homes (i.e., the measurement of new cases of infection (incidence) during a defined period of risk in the patient/resident population, e.g., length of stay in a hospital or long-term care home). Where medical devices are inserted and/or surgical procedures are performed, rates of device-associated or surgical site infection should also be calculated on an ongoing basis. It may be useful in hospitals to stratify rates of surgical site infections by standardized risk scores in order to compare the rates to other hospitals.

An electronic spreadsheet/database and/or statistical analysis program should be used in hospitals and long-term care homes to store data and calculate HAI rates, to maximize infection prevention and control resources and reduce the potential for errors associated with manual calculations.

Interpretation of Data
Surveillance data require interpretation to identify areas where improvements to infection prevention and control practices can be implemented to lower the risk of HAI. Increases to a health care setting’s HAI rate should trigger an investigation to look for changes in the hospital or long-term care home’s activities that may explain the apparent change in the rate of infection. This investigation is particularly essential where major deviations from the baseline HAI rate may indicate the presence of an outbreak. Analysis and interpretation of infection data may be done with the facility’s Infection Prevention and Control Committee or other advisory body to the Infection Control Team.

HAI rates may be compared to both the facility’s own previous HAI rates and benchmarks, or to external standards or benchmarks set by other health care settings. When comparing HAI rates to those of other health care settings, it is essential that the same case finding methods are used, the same case definitions are applied and the same methods for risk stratification are employed. It is a recommended practice that a set of peer facilities that serve a similar case mix, use the same case definitions and similar case finding methods be identified to serve as a comparison group.
Communication of Results
Communication of surveillance data should take place on an ongoing, systematic basis and be targeted to those with the ability to change infection prevention and control practice. Communication may be targeted to:

- a health care setting's Infection Prevention and Control Committee, which provides an aggregate picture of all infections of interest in the hospital;
- a particular patient/resident care area or specialty care area, focused on the risk of specific types of infections that are of importance to these groups;
- patient/resident care staff following the identification of an emerging risk of infection, to remind or notify of the required precautions in infection prevention and control.
- local public health unit when there is a reportable communicable disease event.

Evaluation
Periodic review of the surveillance system should be part of regular Infection Prevention and Control Committee meetings in hospitals and long-term care homes and should include an assessment of the outcomes to which the surveillance system contributes. Evaluation should include how information produced by a surveillance system is used to reduce the risk of health care-associated infection. Outcome evaluation should take place at least annually and a realignment of surveillance objectives undertaken when indicated.

The steps provided in this best practices guide will assist infection prevention and control professionals to develop and implement their surveillance programs in a manner that will permit comparisons with their peers and allow them to quickly detect early increases in health care-associated infections that may indicate the presence of an outbreak.

SSI  Surgical Site Infection
UTI  Urinary Tract Infection
VAP  Ventilator-associated Pneumonia
VRE  Vancomycin-resistant Enterococcus
Glossary of Terms

**Active Surveillance for Health Care-associated Infections**: The direct and vigorous search for information on the occurrence of health care-associated infections in order to detect a change or trend in incidence rate. This is in contrast to passive surveillance, where data are not actively solicited. See also, *Passive Surveillance for Health Care-associated Infections*, below.

**Antibiotic Resistant Organism (ARO)**: A microorganism that has developed resistance to the action of several antimicrobial agents and that is of special clinical or epidemiological significance (e.g., MRSA, VRE).

**Benchmark**: A validated measure that may be used for comparison provided data are collected in the same way as that of the benchmark data. Benchmarks are used to compare HAI rates to data that use the same definitions for infection and are appropriately adjusted for patient risk factors so that meaningful comparisons can be made. Comparing HAI rates to a validated benchmark will indicate whether the rates are below or above the recognized average.

**Canadian Nosocomial Infection Surveillance Program (CNISP)**: The Public Health Agency of Canada’s (PHAC) Centre for Infectious Disease Prevention and Control (CIDPC) and the Association of Medical Microbiology and Infectious Disease (AMMI) Canada partner in this national health care surveillance project. CNISP has two main areas of activity: (1) monitoring of important nosocomial pathogens (e.g., MRSA, C. difficile, VRE, ESBL); and (2) surveillance of specific types of nosocomial infections including those associated with central venous catheters, ventricular shunts and other surgeries. Forty-nine sentinel hospitals, from nine provinces participate in CNISP surveillance projects.

**CHICA-Canada**: The Community and Hospital Infection Control Association of Canada, a professional organization of persons engaged in infection prevention and control activities in health care settings. CHICA-Canada members include infection prevention and control professionals from a number of related specialties including nurses, epidemiologists, physicians, microbiology technologists, public health and industry. The CHICA-Canada website is located at: [http://www.chica.org](http://www.chica.org).

**Complex Continuing Care (CCC)**: Complex continuing care provides continuing, medically complex and specialized services to both young and old, sometimes over extended periods of time. Such care also includes support to families who have palliative or respite care needs. It plays an integral role in the treatment offered in Ontario hospitals.

**Data Mining**: The process of sorting through large amounts of data and picking out relevant information. An example of data mining for surveillance is the extraction of patients with symptoms or diagnostic test results that indicate potential cases with health care-associated infection from large patient information systems.

**Denominator**: Represents the population at risk.

**Endemic**: The constant presence of a disease or infectious agent within a certain area.

**Endemic Rate**: A baseline or expected rate of infection. Knowledge of the endemic rate of infection in a hospital or long-term care home can assist in identifying major deviations from this baseline that may indicate the presence of an outbreak. More importantly, through surveillance, hospitals and long-term care homes can evaluate whether reductions to endemic rates resulted following modifications to infection prevention and control practices.

**Health Care-associated Infection (HAI)**: A term relating to an infection that is acquired during the delivery of health care (also known as *nosocomial infection*).
Health Care Facility: A set of physical infrastructure elements supporting the delivery of health-related services. A health care facility does not include a client/patient/resident’s home or physician offices where health care may be provided.

Health Care Setting: Any location where health care is provided, including settings where emergency care is provided, hospitals, complex continuing care, rehabilitation hospitals, long-term care homes, mental health facilities, outpatient clinics, community health centres and clinics, physician offices, dental offices, offices of allied health professionals, public health clinics and home health care.

Hospital-wide Surveillance: All care areas are continuously and prospectively surveyed for all conditions or events of interest.

Incidence Density: The measurement of new cases of infection (incidence) based on the time at risk in the patient population (e.g., length of stay in hospital, length of exposure to a device). An incidence density rate expresses the risk of infection in ‘person time’, or the amount of time that a person spends at risk.

Incidence Rate: A measurement of new cases of disease occurring within a population over a given period of time. The numerator is the number of new cases detected and the denominator is the initial population at risk for developing the particular infection or event during a given time frame.

Infection Prevention and Control (IPAC): Evidence-based practices and procedures that, when applied consistently in health care settings, can prevent or reduce the risk of transmission of microorganisms to health care providers, other clients/patients/residents and visitors.

Infection Prevention and Control Professional(s)(ICPs): Trained individual(s) responsible for a health care setting’s infection prevention and control activities. In Ontario, an ICP must receive a minimum of 80 hours of instruction in a CHICA-Canada endorsed infection control program within six months of entering the role and must acquire and maintain Certification in Infection Control (CIC®) when eligible. The ICP should maintain a current knowledge base of infection prevention and control information.

Infection Risk: The probability that a patient/resident will acquire an infection based on the characteristics of the individual, the inherent risks associated with a procedure, or other factors that might put the individual at risk for a health care-associated infection.

Inter-rater Reliability: A measurement of the agreement between two individuals, for example in coding or diagnosis. In surveillance of nosocomial infections, the inter-rater reliability for identification of nosocomial infections might be assessed by having two ICPs apply a case definition for infection to a case series of potential infections. The degree of agreement would then be the proportion of cases that were defined in the same way by each ICP.

Long-Term Care (LTC): A broad range of personal care, support and health services provided to people who have limitations that prevent them from full participation in the activities of daily living. The people who use long-term care services are usually the elderly, people with disabilities and people who have a chronic or prolonged illness.

National Healthcare Safety Network (NHSN): A project of the Centers for Disease Control and Prevention that provides aggregate data compiled since 1992 from 300 U.S. acute care settings. NHSN HAI rates may be used for benchmarking acute care HAI rates, provided that the same standardized definitions for infection are used. NHSN results are stratified by patient risk index. More information is available at: http://www.cdc.gov/nhsn/.
**NHSN SSI Risk Index:** A score used to predict a patient’s risk of acquiring a surgical site infection. The risk index score, ranging from 0 to 3, indicates the number of infection risk factors present. One point is scored for each of the following: a) a patient with an American Society of Anesthesiologists’ (ASA) physical status classification score of 3, 4, or 5; b) an operation classified as contaminated or dirty/infected; and c) an operation lasting greater than $T$ hours, where $T$ is the recommended average operation length of time assigned to the operation being performed.

**Nosocomial Infection:** Infection acquired during the delivery of health care within a particular health care facility. See also, *Health Care-associated Infection*, above.

**Numerator:** Each event/infection that occurs during the surveillance period.

**Ontario Agency for Health Protection and Promotion (OAHPP):** An arm’s-length government agency dedicated to protecting and promoting the health of all Ontarians and reducing inequities in health. OAHPP was created by legislation in 2007 and began operations in July 2008 with a mandate to provide scientific and technical advice to those working to protect and promote the health of Ontarians. It’s vision is to be an internationally recognized centre of expertise dedicated to protecting and promoting the health of all Ontarians through the application and advancement of science and knowledge. OAHPP’s operating name is Public Health Ontario (PHO).

**Outbreak:** For the purposes of this document, an outbreak is an increase in the number of cases above the number normally occurring in a particular health care setting over a defined period of time.

**Outcome surveillance:** Surveillance used to measure client/patient/resident outcomes (changes in the client/patient/resident’s health status that can be attributed to preceding care and service). An example of outcome surveillance related to infection prevention and control is surveillance of HAI rates. Outcome surveillance reflects the efficacy of the infection prevention and control program in protecting clients/patients/residents, health care providers and visitors from health care-associated infections while decreasing costs from infections.

**Passive Surveillance for Health Care-associated Infections:** Identification of health care-associated infections through established event reporting procedures by staff whose primary responsibility is patient/resident care. This is in contrast to active surveillance, where data are actively solicited. See also, *Active Surveillance for Health Care-associated Infection*, above.

**Patient/resident:** Any person receiving care within a hospital or long-term care home.

**Periodic Surveillance for Health Care-associated Infections:** Surveillance undertaken over a specified time interval (e.g., one month each quarter) in a health care setting. Some infection prevention and control programs will conduct surveillance on one or more units for a period of time and then shift to another unit or group of units. This rotation provides a less costly method to collect information on all high risk patient care areas.

**Prevalence Survey for Health Care-associated Infections:** Surveillance for all existing and new nosocomial infections in a health care setting either on a single day (*point prevalence*) or over a specified number of days (*period prevalence*). Data from each patient/resident is collected only once. A prevalence survey can provide a rapid, inexpensive way to estimate the global view and magnitude of health care-associated infections in a health care setting at a single point in time. It should also be noted that while a prevalence survey provides a picture of nosocomial infections at a single point in time, this risk estimate can be affected by the context for infection at that time. For instance, a prevalence survey for nosocomial respiratory infections during the winter months may indicate a higher risk of infection due to the seasonal occurrence of these events.
**Process Surveillance:** Surveillance used to assess or measure client/patient/resident processes (things done to or for a patient/resident during their encounter with the health care system). An example of process surveillance related to infection prevention and control is planned audits to verify that procedures and/or standards of practice are being followed.

**Provincial Infectious Diseases Advisory Committee (PIDAC):** A multidisciplinary, scientific advisory body within the OAHPP, that provides evidence-based advice regarding multiple aspects of infectious disease identification, prevention and control. More information is available at: [http://www.pidac.ca](http://www.pidac.ca).

**Public Health Agency of Canada (PHAC):** A national agency that promotes improvement in the health status of Canadians through public health action and the development of national guidelines. The PHAC website is located at: [http://www.phac-aspc.gc.ca](http://www.phac-aspc.gc.ca).

**Public Health Ontario (PHO):** Created June 14, 2011, Public Health Ontario is the operating name for OAHPP.

**Regional Infection Control Networks (RICN):** The RICN of Ontario coordinate and integrate resources related to the prevention, surveillance and control of infectious diseases across all health care sectors and for all health care providers, promoting a common approach to infection prevention and control and utilization of best-practices within the region. There are 14 regional networks in Ontario. More information is available at: [http://www.ricn.on.ca](http://www.ricn.on.ca).

**Risk Stratification:** A process to control for differences in the underlying risk factors for infection. Risk stratification involves calculating separate rates for patients/residents with similar susceptibilities to health care-associated infections, or those in the same category of risk (e.g., surgeon-specific infection rates).

**Sensitivity:** Proportion of persons with true positive results among persons known to have a disease.

**Sentinel Event:** A colonization/infection in which the occurrence of perhaps even a single case may signal the need to re-examine preventive practices.

**Specificity:** Proportion of persons with true negative results among persons without the disease.

**Standard Deviation (SD):** The average distance that a surveillance rate in a particular period can be expected to deviate from the overall mean rate of infection observed in a health care setting. For example, if the mean rate of surgical site infection following hip replacement surgery over a ten-year period in a hospital is 3.5 per 100 procedures with a SD of 1.0, then the rate of infection will be in the range of 2.5 to 4.5 per 100 surgical site infections. A rate of infection that is more than two SD units from the mean rate (e.g., >5.5 per 100 in the above example) is much more than the expected variation in the rate of infection and should prompt immediate investigation. Two SDs represent 95.5% of all results.

**Surveillance:** The systematic, ongoing collection, collation and analysis of data with timely dissemination of information to those who require it in order to take action.

**Syndromic Surveillance:** The detection of individual and population health indicators of illness (i.e., signs and symptoms of infectious disease) that is discernible before confirmed laboratory diagnoses are made.

**Targeted Surveillance:** Surveillance that is focused on certain health care setting areas (e.g., intensive care unit), patient populations (e.g., surgical patients) and/or infection types (e.g., bloodstream infections, indwelling catheter-associated urinary tract infections), that have been identified as a priority within the health care setting.
Preamble

About this Document

This document is intended as a guide for Infection Control Professionals in acute and long-term care, to ensure that the critical elements and methods of surveillance for health care-associated infections (HAIs) are incorporated into their practice. It provides guidance for each of the building blocks of the surveillance system including planning, data collection, interpretation, analysis and communication, to inform infection prevention and control practices that will result in effective surveillance in hospitals and long-term care homes.

The best practices for surveillance described in this document should assist acute and long-term care settings in Ontario in establishing surveillance systems. Effective surveillance should lead to process improvements that will result in decreases in HAI rates, morbidity, mortality and health care costs. Although the primary audience for this document comprises those directly involved in surveillance, it also serves as a resource for anyone seeking to improve their understanding of best practices in nosocomial infection surveillance.

The best practices in this document recommend a standardized approach to the surveillance of health care-associated infections that will allow for the comparison of rates within facilities, across facilities as well as comparison to provincial and national benchmarks. This document forms one component of an effort to enhance patient safety and improve the quality of health care in Ontario.

Evidence for Recommendations

The principles and practices recommended in this document are a synthesis of the best available scientific evidence and expert opinion of professionals from the fields of infectious diseases, infection prevention and control, public health and epidemiology. As new information becomes available, recommendations in this document will be reviewed and updated.

How and When to Use This Document

The types of health care settings to which the guidance provided in this document applies are outlined in Box 1.

Box 1: Health Care Settings Impacted by this Document

This document applies to these health care settings:
- Hospitals (tertiary care, community care, mental health, rehabilitation, etc.)
- Long-term/chronic care homes
- Complex continuing care settings

This document does not apply to these health care settings:
- Primary care
- Community health settings (clinics, physician offices, dental offices)
- Home health care
Limitations to this Document

This document deals with the surveillance of infections that result as an outcome of health care, rather than on the processes contributing to changes in the risk of acquiring health care-associated infections. Monitoring of processes, such as hand hygiene and sterilization techniques, are addressed through the health care setting’s practice audits, rather than through the outcome surveillance systems as described in this best practices guide. For more information regarding process surveillance, see the Provincial Infectious Diseases Advisory Committee (PIDAC)’s Best Practices for Infection Prevention and Control Programs in Ontario in All Health Care Settings.3

This document does not proscribe how much surveillance should be done in individual facilities, nor does it dictate what should be surveyed. It is acknowledged that different facilities may implement these best practices in different ways, depending on resources and local circumstances. For more information regarding recommendations for surveillance targets, see PIDAC’s Best Practices for Infection Prevention and Control Programs in Ontario in All Health Care Settings.3

This document provides guidance for routine surveillance programs and is not intended as a guide for infection surveillance during outbreaks. However, it is recognized that baseline HAI rates established by a well-functioning, ongoing surveillance system are essential to assist in outbreak identification by indicating increases above the norm. Once an outbreak is suspected, health care settings must notify their local Medical Officer of Health (institutional outbreaks are reportable under the Health Protection and Promotion Act4) and outbreak management should be undertaken in collaboration with the local public health authorities.

Specific surveillance recommendations for antibiotic-resistant microorganisms and Clostridium difficile are not included in this document. Refer to the following Ontario documents for examples of specific surveillance methodologies:

Illustrations and Symbols

Throughout the document, illustrations are used to demonstrate the concepts described in the text. These illustrations are meant as examples of how the recommended best practices outlined in this document could be applied in an acute and a long-term care setting. The illustrations used are:

- City General Hospital – a fictitious acute care hospital
- Forest Manor – a fictitious long-term care home

The following symbols are used throughout the document:

**Recommended Best Practices** are annotated with this symbol. These practices are recommended by PIDAC based on the best available evidence as a standardized approach to surveillance. All recommended best practices are summarized at the end of the document.

**Pearls of Wisdom** are annotated with this symbol and provide lessons from those with longstanding experience in the field of surveillance. Pearls of wisdom draw attention to commonly overlooked areas and, in some cases, common pitfalls in undertaking surveillance.

**Surveillance Tools** are annotated with this symbol and refer to a set of practical tools that may be used to implement the recommended best practices.

Assumptions and General Principles

The best practices in this document are based on the assumption that basic infection prevention and control systems are in place in health care settings in Ontario. Without a basic system of infection prevention and control in place, appropriate resources for surveillance system planning, data collection and analysis as well as improvements to infection prevention and control practices based on the information provided by the surveillance system will be difficult to identify. Collaboration with organizations that have infection prevention and control expertise, such as academic health science centres, regional infection control networks, public health units that have professional staff certified in infection prevention and control and local infection prevention and control associations (e.g., Community and Hospital Infection Control Association – Canada chapters) may be necessary to develop evidence-based programs.

In addition to the general assumption (above) regarding basic infection prevention and control, these best practices are based on the following additional assumptions and principles:

1. Adequate resources are devoted to infection prevention and control in all health care settings. See PIDAC’s Best Practices for Infection Prevention and Control Programs in Ontario in All Health Care Settings, available at: http://www.oahpp.ca/resources/pidac-

See also Ontario’s hand hygiene improvement program, Just Clean Your Hands, available at: http://www.health.gov.on.ca/en/ms/handhygiene/.

3. Adequate resources, including human resources, are devoted to Environmental Services/Housekeeping in all health care settings to enable written procedures for cleaning and disinfection of patient rooms and equipment; education of new cleaning staff and continuing education of all cleaning staff; increased capacity for outbreak management; and ongoing review of procedures. See PIDAC’s Best Practices for Environmental Cleaning in All Health Care Settings, available at: http://www.oahpp.ca/resources/pidac-knowledge/best-practice-manuals/environmental-cleaning-for-prevention-and-control-of-infections.html.

6. Regular education (including orientation and continuing education) and support to help staff consistently implement appropriate infection prevention and control practices is provided in all health care settings. Effective education programs emphasize:

- the risks associated with infectious diseases, including acute respiratory infection and gastroenteritis;
- hand hygiene, including the use of alcohol-based hand rubs and hand washing;
- principles and components of Routine Practices as well as additional transmission-based precautions (Additional Precautions);
- assessment of the risk of infection transmission and the appropriate use of personal protective equipment (PPE), including safe application, removal and disposal;
- appropriate cleaning and/or disinfection of health care equipment, supplies and surfaces or items in the health care environment;
- individual staff responsibility for keeping patients, themselves and co-workers safe; and
- collaboration between professionals involved in Infection Prevention and Control (IPAC) and Occupational Health and Safety (OHS).

**NOTE:** Education programs should be flexible enough to meet the diverse needs of the range of health care providers and other staff who work in the health care setting. The local public health unit and regional infection control networks may be a resource and can provide assistance in developing and providing education programs for community settings.
7. Collaboration between professionals involved in OHS and IPAC is promoted in all health care settings to implement and maintain appropriate infection prevention and control standards that protect workers.

8. There are effective working relationships between the health care setting and the local public health unit. Clear lines of communication are maintained and public health is contacted for information and advice as required and the obligations (under the Health Protection and Promotion Act, R.S.O. 1990, c.H.7) to report reportable and communicable diseases is fulfilled. Public health provides regular aggregate reports of outbreaks of any infectious diseases in facilities and/or in the community to all health care settings.

9. Access to ongoing infection prevention and control advice and guidance to support staff and resolve differences is available to the health care setting.

10. There are established procedures for receiving and responding appropriately to all international, national, regional and local health advisories in all health care settings. Health advisories are communicated promptly to all staff responsible for case finding/surveillance and regular updates are provided. Current advisories are available from local public health units, the Ministry of Health and Long-Term Care (MOHLTC), Health Canada and Public Health Agency of Canada websites as well as local regional infection prevention and control networks.

11. Where applicable, there is a process for evaluating personal protective equipment (PPE) in the health care setting, to ensure it meets quality standards.

12. There is regular assessment of the effectiveness of the infection prevention and control education program and its impact on practices in the health care setting. The information is used to further refine the program.

13. Occupational Health and Safety requirements shall be met:

- Health care facilities are required to comply with applicable provisions of the Occupational Health and Safety Act (OHSA), R.S.O. 1990, c.0.1 and its Regulations. Employers, supervisors and workers have rights, duties and obligations under the OHSA. Specific requirements under the OHSA are available at: [http://www.elaws.gov.on.ca/html/statutes/english/elaws_statutes_90o01_e.htm](http://www.elaws.gov.on.ca/html/statutes/english/elaws_statutes_90o01_e.htm).

- Specific requirements for certain health care and residential facilities may be found in the Regulation for Health Care and Residential Facilities, available at: [http://www.elaws.gov.on.ca/html/regs/english/elaws_regs_930067_e.htm](http://www.elaws.gov.on.ca/html/regs/english/elaws_regs_930067_e.htm).

- In addition, the OHSA section 25(2)(h), the ‘general duty clause’, requires an employer to take every precaution reasonable in the circumstances for the protection of a worker. There is a general duty for an employer to establish written measures and procedures for the health and safety of workers, in consultation with the joint health and safety committee or health and safety representative, if any. Such measures and procedures may include, but are not limited to, the following:
- safe work practices;
- safe working conditions;
- proper hygiene practices and the use of hygiene facilities; and
- the control of infections.

- At least once a year the measures and procedures for the health and safety of workers shall be reviewed and revised in the light of current knowledge and practice. The employer, in consultation with the joint health and safety committee or health and safety representative, if any, shall develop, establish and provide training and educational programs in health and safety measures and procedures for workers that are relevant to the workers’ work.

- A worker who is required by his or her employer or by the Regulation for Health Care and Residential Facilities to wear or use any protective clothing, equipment or device shall be instructed and trained in its care, use and limitations before wearing or using it for the first time and at regular intervals thereafter and the worker shall participate in such instruction and training. The employer is reminded of the need to be able to demonstrate training, and is therefore encouraged to document the workers trained, the dates training was conducted, and materials covered during training. Under the Occupational Health and Safety Act, a worker must work in compliance with the Act and its regulations, and use or wear any equipment, protective devices or clothing required by the employer.

➢ For more information, contact your local Ministry of Labour office. A list of local Ministry of Labour offices in Ontario may be found at [http://www.labour.gov.on.ca/](http://www.labour.gov.on.ca/).

Purpose of Surveillance

With the emergence antibiotic-resistant organisms (AROs) in health care settings, increasingly immunocompromised patients in acute care and increasing numbers of individuals requiring long-term care and complex continuing care, health care-associated infections (HAIs) represent an important and growing challenge to the entire health care system. A large proportion of HAIs are preventable and the scientific literature has established that incorporating surveillance systems into infection prevention and control activities are a means to reduce the frequency of these events. Surveillance is also useful in monitoring the effectiveness of preventive and infection control programs and is required for patient safety and mandatory reporting requirements in Ontario.

What is a Surveillance System?

Surveillance is defined as “the ongoing, systematic collection, analysis, interpretation and evaluation of health data closely integrated with the timely dissemination of this data to those who need it”. There are two key aspects of surveillance systems:

- Surveillance is an organized and ongoing component of a program to improve a specific area of population health.
- Surveillance systems go beyond the collection of information; they involve mechanisms through which the knowledge gained through surveillance is delivered to those who can use it to direct resources where needed to improve health.

RATIONALE FOR SURVEILLANCE SYSTEMS IN ACUTE AND LONG-TERM CARE SETTINGS

HAIs are a major and continuing challenge in hospitals and long-term care homes. It is estimated that 220,000 infections are acquired in hospitals each year in Canada, resulting in 8,000 deaths. HAIs are also very costly, with a US estimate of $4 billion and a UK estimate of 900 million pounds associated with the prolonged stay and treatment costs for infections acquired in hospitals per year. The rapid increase of AROs has added to the impact of HAIs. Canadian surveillance data shows a greater than five-fold increase in the rates of methicillin-resistant Staphylococcus aureus (MRSA) in hospitals since 1995. The recent increase of Clostridium difficile infection (CDI) is also associated with substantial excess morbidity, mortality and health care costs. Miller et al noted the frequent occurrence of medical complications and mortality associated with nosocomial CDI. The hospital care and drug costs associated with nosocomial CDI readmissions alone were projected at $128,500 per hospital per year in Canada.

HAIs are also common in long-term care homes, frequently resulting in death. Estimates of the rates of HAI in long-term care homes range from 1.8 to 13.5 per 1000 patient care days, which is comparable to that in the hospital setting. As the numbers of individuals requiring long-term care is expected to rise dramatically in the coming years, increased resources for infection prevention and control in this care setting will be an important factor to overall health.
It is estimated that between 30% and 50% of HAIs are preventable.\textsuperscript{14, 21-24} Therefore, an infection prevention and control program that is effective in preventing HAIs can substantially reduce health care costs and, more importantly, the morbidity and mortality associated with HAIs.

**EVIDENCE TO SUPPORT BEST PRACTICES IN SURVEILLANCE**

A surveillance system in hospitals and long-term care homes forms an integral part of an infection prevention and control program aimed at reducing health care-associated infections. In order to demonstrate the impact of surveillance on nosocomial infections in health care settings, a critical appraisal of the evidence documenting changes to the risk of infection following the establishment of a surveillance system was undertaken:

- A systematic review of the scientific literature identified 12 studies that examined changes in the rates of nosocomial infections following the introduction of nosocomial surveillance.\textsuperscript{24-35}
- The studies compared the risk of nosocomial infection at the beginning of a surveillance program (before any impacts associated with the program could be expected) to the risk of infection after the surveillance program was established and operational.
- There was a clear connection between implementation of a surveillance program and subsequent decline in the rates of nosocomial infection.\textsuperscript{35} Reductions in the rates of nosocomial infections generally ranged from 7% to 60% following the implementation of surveillance programs.
- Several of the studies indicated that the reductions in rates of nosocomial infections were the result of changes to infection prevention and control practices informed by the feedback provided by the surveillance system.\textsuperscript{26, 28, 33-35}

Refer to Appendix A for the methods used to conduct this review and the evaluative criteria applied to the studies.

There are many mechanisms through which surveillance reduces the risk of nosocomial infection in hospitals. The *Hawthorne Effect* (i.e., practices improve when increased attention is brought to them) may play a major role. Also, the presence of an Infection Control Professional (ICP) in a particular care area may increase dialogue and awareness of standards for infection prevention and control.

Haley’s 1980’s landmark *Study on the Efficacy of Nosocomial Infection Control (SENIC Project)*\textsuperscript{36} demonstrated that a comprehensive, organized surveillance system with a physician trained in infection prevention and control and one ICP per 250 patient beds was associated with reduced rates of nosocomial infection.\textsuperscript{24} Haley’s study also found that feedback of infection rates to surgeons was an essential surveillance component to reduce surgical site infection. Both Canadian and US expert panels have used SENIC as a basis for their recommendations for essential infrastructure and personnel resources for infection prevention and control in hospitals and long-term care homes since the publication of this study.

In recent years, an inventory of resources for surveillance and infection prevention and control activities, *Resources for Infection Control in Canadian Hospitals (RICH)*, conducted by Zoutman et al, found that a substantial proportion of hospitals still lack the essential resources to carry out surveillance.\textsuperscript{37} RICH data also demonstrated that Canadian hospitals with sophisticated surveillance systems experienced lower rates of infections caused by antibiotic-resistant organisms.\textsuperscript{38} The RICH study has recently been expanded to long-term care with similar findings relating to inadequately developed surveillance systems.\textsuperscript{39}

Current recommendations for infection prevention and control resources take into account the complexity of today’s health care settings and varied case mixes.\textsuperscript{22, 40} More information may be
Elements of Surveillance

Surveillance systems for infections in acute and long-term care homes serve several related purposes towards the end goal of reducing the risk of acquiring health care-associated infection:

**DETECT AND MONITOR**

A well-functioning surveillance system provides the means to establish the endemic, or baseline, rate of nosocomial infection in a health care setting. The vast majority (90-95%) of nosocomial infections do not occur within the context of an identified outbreak, but reflect areas where improvements may be made that will result in a sustained lowering of the endemic rate. While surveillance can assist in the detection of outbreaks in hospitals and long-term care homes by identifying significant deviations from the baseline rate, a more central purpose of ongoing surveillance is to monitor changes in the endemic rate of infection that indicate areas to focus improvements.

**IDENTIFY RISK FACTORS FOR HEALTH CARE-ASSOCIATED INFECTION**

The data collected as part of a surveillance system in a health care setting can be used to identify patients or residents at high risk for nosocomial infections or practices associated with a high risk of infection. For example, the U.S. National Healthcare Safety Network (NHSN) data have been used to compare the risk of surgical site infection among patients undergoing open vs. laparoscopic cholecystectomy.

Risk factors for nosocomial infection, such as urinary incontinency, presence of an indwelling catheter, skin ulcers and chronic conditions such as heart disease, have all been identified in the long-term care context through the use of surveillance data.

**EVALUATE PREVENTIVE INTERVENTIONS**

Following the implementation of preventive practices, data from the surveillance system can be used to investigate whether the measures were effective in achieving their intended outcome of improved infection control. Data collected through surveillance can also identify ineffective infection prevention and control measures, an example of which is provided in Box 2.
The continued presence of a surveillance system can increase awareness of infection prevention and control practices through discussions initiated by ICPs as they gather information from wards. Barwolff et al noted that the decrease in rates of surgical site infection following Caesarean delivery in several German hospitals was attributed to the increased awareness of the risks of surgical site infection and of standards in infection prevention and control generated by the presence of the surveillance program in the obstetrics wards.\textsuperscript{32}

Regular contact with ICPs can also identify areas where changes to infection prevention and control practices could lower the rates of infection in high risk areas. For example, regular contact of ward nurses with the ICP in a long-term care home over the course of an influenza season can serve to remind staff of appropriate infection prevention and control practices (e.g., cohorting, droplet precautions) for residents developing ‘influenza-like’ illnesses (ILIs).

Evidence of the effectiveness of preventive interventions in one’s own health care setting also serves to reinforce practice. The use of surveillance data from one’s own facility, demonstrating the effect of infection prevention and control practices on nosocomial infections, can be successful in building awareness of the benefits of preventive practices.

**Best Practices**

Different health care settings serve different patient populations, offer different diagnostic procedures and treatments and have a varying proportion of care that is offered in inpatient vs. outpatient settings. As a result the priorities, goals and information needs of a surveillance system will vary across health care settings. Additionally, the resources available for the establishment and operation of a surveillance system are also expected to vary by facility.

The general steps required in setting up a surveillance program can be followed by any hospital or long-term care home in planning and implementing their surveillance system:

- assess the population to be surveyed;
- select the outcome(s) for surveillance;
- establish case definitions for infection;
- collect the surveillance data;
- calculate and analyze surveillance rates;
- apply risk stratification methodology where applicable;
- interpret HAI rates;
- communicate and use surveillance information to improve practice; and
- evaluate the surveillance system.

**Box 2: Example of the Use of Surveillance to Identify Ineffective Practices:**

*Discontinuation of Pre-operative Shaving Practices*

In two Calgary hospitals, pre-operative shaving with razor of the intended surgical wound site was found to be associated with a higher risk of surgical site infection. Although pre-operative shaving was once thought to reduce the risk of surgical site infection, information provided by the surveillance system demonstrated a sustained decline in the risk of surgical site infection in both hospitals following the discontinuation of this practice.\textsuperscript{Cruse PJ, Surg Clin North Am 1980}
Figure 1 illustrates these recommended steps within the planning, data collection, analysis, interpretation, communication and evaluation phases of surveillance.

**Figure 1: Steps to planning a surveillance system**

**ASSESS THE POPULATION TO BE SURVEYED**

As each health care setting serves different types of patients/residents who face varying levels of risk for different types of infections, an evaluation of the populations served by the hospital or long-term care home should be a first step in planning a surveillance system. This evaluation enables priorities for a surveillance system to be established. Resources for surveillance can be then targeted to the populations at risk for the outcomes of greatest importance, defined in these priority areas.
How to Assess the Population Served by a Health Care Setting

Box 3 outlines the types of questions that can assist in the assessment of a patient population:

<table>
<thead>
<tr>
<th>Box 3: Questions Assisting in Assessment of Populations Served by a Particular Hospital or Long-term Care Home</th>
</tr>
</thead>
<tbody>
<tr>
<td>✓ What is the catchment area of the hospital or long-term care home?</td>
</tr>
<tr>
<td>✓ What types of patients/residents are served (e.g., age distribution, sociodemographic profile)?</td>
</tr>
<tr>
<td>✓ What are the most common diagnoses?</td>
</tr>
<tr>
<td>✓ What are the most frequently performed invasive procedures (e.g., surgeries for hospitals, indwelling urinary catheters for long-term care homes)?</td>
</tr>
<tr>
<td>✓ Which services or treatments are utilized most frequently?</td>
</tr>
<tr>
<td>✓ What types of patients/residents are at greatest risk of infection?</td>
</tr>
<tr>
<td>✓ Are there any health concerns emerging from the community (e.g., community-associated MRSA, tuberculosis)?</td>
</tr>
</tbody>
</table>

The use of information resources specific to a particular hospital or long-term care home should be used to address these questions. Examples of some of the information resources that may be used to assess a population include:

- medical records;
- financial services or information services reports;
- surgical databases;
- administrative/management reports;
- community health status reports, produced by local public health units (to identify health concerns from the surrounding community); and
- census reports.

Information on the demographic characteristics of the population served by a health care setting, such as its age distribution, socioeconomic conditions and ethnic diversity, can be obtained from the health care setting’s census reports.

Recommended Best Practice #1:
As a first step in the planning of a surveillance system, it is a recommended practice that a health care setting assess:

- the types of patients/residents that it serves;
- the key medical interventions and procedures that they undergo; and
- the types of infections for which they are most at risk.

This assessment is done to establish priorities for the surveillance system.
SELECT THE OUTCOMES FOR SURVEILLANCE

Selection of the types of infections that will be surveyed should be undertaken in conjunction with an assessment of the population and identification of surveillance priorities as described above. Most infection prevention and control programs have prioritized the types of infections for surveillance that have the most important impact on the populations that they serve.

1. Facility-wide Surveillance

Facility-wide surveillance of all infections is not recommended in health care settings. Facility-wide surveillance involves the prospective and continuous survey by the ICP (or the person to whom responsibility for surveillance has been designated) of all care areas of the hospital or long-term care home for all instances of infection. The ICP also follows up frequently with nursing and other staff (daily, if possible) and occasionally with patients/residents in all areas of the health care setting. Facility-wide surveillance, while comprehensive, requires considerable time and personnel resources. There is no value to identifying infections for surveillance purposes unless the results may be used to effect change that will result in lower HAI rates. Facility-wide surveillance will identify many infections that cannot be prevented, wasting valuable resources that may be used for other purposes, such as education. Prioritization of the types of infections to be surveyed will assist the ICP to make the best use of the available resources while having the greatest impact on the populations that they serve.

**Pearl of Wisdom:** Health care settings will not find it feasible to conduct surveillance of all infections in all patients/residents at all times. Prioritization of the most important infections to be included in a surveillance system will be necessary.

2. General Considerations for Surveillance Choices

The choice of which infections to monitor by surveillance may be determined by several factors:

- Mandatory - the health care setting may be mandated to monitor specific infections (e.g., required for accreditation review or to comply with PIDAC’s recommended best practices).
- Incidence - a particular type of infection may be of special concern in the health care setting due to its frequency.
- Communicability - a particular pathogen may be of concern in the health care setting due to its communicability.
- System/patient cost - the infection has associated impacts and costs indicated by:
  - the frequency with which the infection results in mortality (its case-fatality ratio);
  - prolonged hospital stay resulting from the infection;
  - issues with transfers to non-hospital settings; and
  - the excess treatment costs associated with the infection.
Effectiveness of intervention - surveillance for a particular infection will assess the effectiveness of infection prevention and control interventions.

Early detection - syndromic surveillance (e.g., acute respiratory illness or respiratory symptoms indicative of an infectious process, acute gastrointestinal illness) is universally recommended in hospitals and long-term care homes and has the added benefit of detecting important health care-associated infections, such as CDI.

Boxes 4 and 5 illustrate how different types of health care settings may undertake the population assessment and selection of outcomes for surveillance programs.

**Box 4: Population Assessment and Selection of Surveillance Outcomes (acute care example)**

City General Hospital is a fictitious 550-bed tertiary care facility serving a wide catchment area that includes several surrounding rural communities. City General hospital houses a regional cancer centre and trauma centre and serves some of the region’s most critically ill patients. City General Hospital targets high risk patients and undertakes surveillance of all patients in the ICU for two types of device-associated infections:

- ventilator-associated pneumonias; and
- central venous catheter-associated bloodstream infections.

Total hip and knee replacements, laminectomies and coronary artery bypass grafts (CABG) are among the most common surgical procedures undertaken at City General Hospital. These have been selected for surveillance due to the severe complications associated with surgical site infection following these procedures. Also, with the presence of the cancer centre, colectomies and abdominal hysterectomies have also been selected for surgical site infection surveillance.

With its wide catchment area and the critically ill patient groups that it serves, City General Hospital also tracks the frequencies of both colonization and infection with antibiotic-resistant organisms (AROs).

**Box 5: Population Assessment and Selection of Surveillance Outcomes (long-term care example)**

Forest Manor is a fictitious 100-bed long-term care home. Half of all residents are dependent on staff for assistance to carry out normal activities associated with daily living.

Symptomatic urinary tract infections (UTIs) comprise one-third of nosocomial infections and 10% of residents have urethral catheters. Lower respiratory tract infections account for half of the remaining nosocomial infections. Approximately 20% of infections developed by residents at Forest Manor are skin and soft tissue infections.

Forest Manor conducts surveillance of lower respiratory tract infections, skin and soft tissue infections and UTIs associated with indwelling catheters. Forest Manor also tracks the percentage of residents receiving annual influenza vaccine to assess how vaccine uptake correlates with lower respiratory tract infections in the resident population.
3. Selection of Outcomes in Acute Care

What tools can be used to assist in selecting the outcomes for surveillance?

Table 1 illustrates a hypothetical set of data on the frequency, impacts, costs and preventability of four common health care-associated infections in a fictional hospital. The data presented in Table 1 can be collected as a first step in surveillance planning through the use of a prevalence survey.

A prevalence survey is a surveillance tool that takes inventory of all active (existing and new) infections at a single point in time. Data from each patient are collected only once, on a single day or over the course of a set number of days.

Table 1: Sample hospital dataset used to assist with prioritization of health care-associated infections selected for surveillance

<table>

</table>

A hospital may select its surveillance outcomes based on other factors that are important to the facility. For example, a hospital facing frequent acute care bed shortages may rank infections resulting in prolonged hospital stay as an effective allocation of surveillance resources.

Once selected, a hospital’s infection outcomes and associated resource allocations in surveillance are not necessarily fixed. For example, based on the data in Table 1, the hospital may not choose to routinely undertake comprehensive surveillance of urinary tract infections (UTIs), but may still monitor this type of infection through reviews of urine culture test results from laboratory reports, looking for detection of unusual trends or clustering of
cases. Changes in the population served by a hospital, the services it offers, or the changing epidemiology of a particular pathogen may change the risk of acquiring specific health care-associated infections and prompt a reassessment of surveillance objectives and a reallocation of surveillance resources. Surveillance objectives should be re-evaluated as needed, at least annually.

4. Selection of Outcomes in Long-term and Chronic Care

In long-term care homes, preventable infections may significantly influence the choice of outcomes for surveillance:

- **Acute respiratory infection/febrile respiratory infection**: In long-term care homes, lower respiratory tract infections, such as influenza, are associated with high morbidity, mortality and disruptions to long-term care services. Surveillance for acute respiratory infection in residents of long-term care homes is universally recommended.

- **Skin and soft tissue infections**: Another important constituent of the burden of health care-associated infections in long-term care homes is skin and soft tissue infections. Many of these infections are preventable, particularly where they result from skin breakdown and pressure ulcer development. Consideration should be given to monitoring skin and soft tissue infections, a common quality of care indicator used in acute, long-term and chronic care settings. Surveillance of skin breakdown provides an opportunity for collaboration of health care providers with the infection prevention and control team to reduce the incidence of soft tissue infections.

- **Urinary tract infection**: In long-term and chronic care settings, many UTIs may be prevented through the limited use of indwelling urinary catheters. These infections contribute significantly to the burden of health care-associated infections in long-term care homes.

**Recommended Best Practice #2:**

Syndromic surveillance of respiratory infections and gastroenteritis should be undertaken in all hospitals and long-term care homes.

Where hospitals and long-term care homes select outcomes for surveillance in addition to the infections listed above, the following should be considered:

- the frequency of the infection;
- the impacts of the infection (including percent case fatality and excess costs associated with the infection); and
- the preventability of the infection.

In both hospitals and long-term care homes, the outcomes selected for surveillance should be re-evaluated at least annually.

**ESTABLISH CASE DEFINITIONS FOR INFECTION**

In any surveillance system, all elements of the data that are being collected need to be clearly defined, including the infection outcome, the ‘at risk’ population and other risk factors for infection. This section outlines the recommended best practices in choosing a case definition for infection.
1. Case Definitions for the Hospital Setting

The NHSN program’s case definitions are used widely in hospital surveillance programs worldwide. The NHSN case definitions for urinary tract infections, bloodstream infections, pneumonias and other infections are provided in Appendix B.

It is a recommended best practice that hospitals use the NHSN case definitions for surveillance purposes. The use of these definitions allows for comparability of findings and benchmarking with other similar hospitals that also use the NHSN definitions. Hospitals participating in the Canadian Nosocomial Infection Surveillance Program (CNISP) also use case definitions that have been developed for that program. Benefits to using established, standardized case definitions include:

- The validity and reliability of the NHSN case definitions have been well established.\(^{48,49}\) If hospitals choose to develop their own case definitions, they will not have the benefit of using definitions that have been reviewed and validated.
- If a hospital uses its own definitions and at a future date decides to switch to the NHSN definitions, the new data will no longer be comparable to previous rates calculated using the earlier case definitions.
- Hospitals that are similar in size and care level and that use the same case definitions can pool their data to investigate risk factors for infection or practices that may be effective in preventing nosocomial infections. This is particularly useful when there may be an insufficient number of cases within a single health care setting to provide meaningful results.

Pearl of Wisdom: Hospitals using the NHSN case definitions benefit from:

- a set of definitions that have been reviewed and validated; and
- surveillance data that can be compared to or pooled with other similar hospitals using the same case definitions.

Box 6 provides an example of the case definitions chosen by a fictitious hospital:

**Box 6: Establishment of Case Definitions (acute care example)**

City General Hospital conducts surveillance for primary bloodstream infections associated with the use of central venous catheters (CVC) and for ventilator-associated pneumonias among ICU patients. The NHSN case definitions are used to allow for comparison of findings and benchmarking with other similar hospitals involved in the regional nosocomial infection surveillance program. Patients eligible for this surveillance are adult ICU patients with one or more CVCs and/or patients on ventilator support.
2. **Case Definitions for the Long-term Care Setting**

Case definitions have been developed by a Canadian Consensus Conference for use in long-term care homes. These definitions were developed taking into account the unique limitations of long-term care surveillance (e.g., lack of radiology and microbiology data). The case definitions for long-term care are presented in Appendix C. It is a recommended best practice that the case definitions from Appendix C be incorporated into surveillance programs in the long-term care setting.

*Box 7* provides an example of the case definitions chosen by a fictitious long-term care home:

---

**Box 7: Establishment of Case Definitions (long-term care example)**

*Forest Manor conducts surveillance for UTIs associated with indwelling catheters and uses the recommended case definitions for long-term care homes (see Appendix C), which include only symptomatic infections. Forest Manor also undertakes surveillance for skin and soft tissue infections and lower respiratory tract infections and uses the recommended case definitions for long-term care homes, which are based on signs and symptoms of infection.*

---

**Recommended Best Practice #3:**

Hospitals should use the NHSN case definitions for nosocomial infections provided in Appendix B. Long-term care homes should use the Canadian Consensus Conference definitions for health care-associated infections in long-term care provided in Appendix C.

3. **Applying Case Definitions**

Once case definitions have been established, steps should be taken to ensure that they are consistently applied. The case in *Box 8* illustrates the potential consequences of inconsistently applied case definitions:
Box 8: Consequences of Inconsistently Applied Case Definitions for Nosocomial Infections

In a U.S. community hospital, a surgeon was repeatedly investigated by the hospital’s infection control team searching for explanations for an elevated infection rate among patients undergoing laminectomy. The surgeon was prepared to discontinue his practice when strict attention to infection control procedures did not result in a decrease in the rates of infection.

Upon further examination it was found that the surveillance case definition used to collect data on the surgeon’s patients included all those who had a positive culture, with or without symptoms of infection. For other surgeons, the case definition required positive cultures plus clinical signs of infection. Hence, patients who were only colonized with bacteria had been included in this surgeon’s rate of infection, making it appear high.

The high rates of infection were deemed the result of surveillance error, not of poor operative technique, and the surgeon did not abandon his practice. This case emphasizes the importance of uniform application of case definitions.

Ehrenkranz NJ, Infect Control Hosp Epidemiol 1995

4. Ensuring that Case Definitions are Consistently Applied

Infection Control Professionals should receive training in the consistent and correct application of case definitions for surveillance. Periodically, the reliability in application of case definition among ICPs should be assessed. This can be accomplished by having ICPs independently apply case definitions to a set of potential infections. Subsequently the inter-rater reliability, or proportion of cases deemed indicative of infection by both ICPs, can be assessed. See Step 9, “Evaluate the Surveillance System” for more information about reliability testing.

Recommended Practice #4:
Hospitals and long-term care homes should take steps to ensure that case definitions are consistently and accurately applied.

5. Determining if an Infection was Associated with Health Care

When a particular infection meets a case definition, it should only be considered nosocomial if it was not present or incubating when the patient/resident was admitted to the hospital or long-term care home. The following criteria may assist in determining if an infection is associated with health care:

- An infection is not considered nosocomial if it represents a complication or extension of an infectious process that was present at admission.
- Infections that occur more than 48 to 72 hours after admission, and within 10 days following discharge, are considered to be associated with health care.
Molecular typing, if available, may provide the ability to distinguish between circulating strains of a microorganism (e.g., MRSA) in order to assess accountability.

In long-term care homes, in order for an infection to be considered nosocomial:

- There must be no evidence that the infection was present on admission to the facility or readmission (following hospitalization or community visit); and
- There must be no evidence that the infection resulted from a procedure performed at an acute care hospital or in a physician’s office.

Determining whether an infection was associated with the care received within the health care setting can represent a major challenge for long-term care homes where residents regularly attend day programs or other activities in the community. When there is uncertainty about whether the infection occurred in community or the long-term care home, the ICP should count a case as “nosocomial”.

Many bacterial infections typically become apparent within 48 hours following infection. This general timeframe is modified for bacterial or viral infections known to have shorter (e.g., Norovirus) or longer (e.g., hepatitis C) incubation periods. Because the incubation period varies by pathogen and, to some extent, the underlying condition of the patient, it is necessary that each infection be assessed individually for its links to hospitalization or, for long-term care residents, the likelihood that the infection was acquired within the long-term care home.

The most important consideration is that a consistent definition for health care-associated infection be used, in order to assess trends over time as part of a facility’s internal benchmarking system.

Pearl of Wisdom: Hospitals and long-term care homes must consider the incubation period for a particular infection and the likelihood that it was acquired in the health care setting when deciding whether a particular case is nosocomial.

COLLECT THE SURVEILLANCE DATA

The goals and outcomes of the surveillance system and the case definitions established in the previous section will determine the data required by the surveillance program. Health care-associated infections are expressed as a rate, i.e., the number of cases as well as the number of persons at risk over a particular period of time. Three elements are required to generate these HAI rates:

- the number of cases (i.e., persons developing a particular infection);
- number of persons at risk (i.e., population at risk for development of that infection); and
- the time period involved.

Because health care settings will have differing priorities for surveillance and resources available to them, case finding may vary from facility to facility. The following procedures provide a guide that may be followed when collecting the data required for the surveillance program based on its objectives and available resources:
1. Review and select sources of data/information for the numerator (number of cases) and denominator (number of persons and/or period of time at risk).
2. Assess the sensitivity and specificity of the data sources and maximize these two parameters.
3. Choose the most feasible surveillance system for the health care setting.
4. Implement the data collection system.
5. Review the information to ensure the dataset is complete (e.g., ensure that a particular physician or service does not forget to report their cases).

1. **Review and Select Sources of Data/Information for the Numerator and Denominator**

   The infection prevention and control team should examine the sources of data available to them and select the method(s) of case finding that will provide all of the information required for the case definitions that it has selected for use in its surveillance system. Most established case definitions for health care-associated infections, such as NHSN or Canadian Consensus Conference case definitions, require a combination of both clinical information (i.e., signs and symptoms of an infection) and diagnostic information (e.g., laboratory results, radiological data) on the patient/resident.

   **A. Numerator Data Collection in Hospitals**

   What sources of data are available for case finding in hospitals?

   Sources of data that are commonly used for case finding in the acute care setting with their associated benefits and limitations are presented in Table 2.

   **Pearl of Wisdom:** Total chart review is not recommended as a case finding method in acute care settings due to the significant time required to obtain data. Different sources of information should be strategically combined to quickly identify potential infections, then further investigation and follow-up is conducted to confirm infection through total chart review and/or consultation with physicians.

</table>
| Total chart/medical record review | ICP reviews medical and nursing notes, medications, treatment records, radiology and laboratory reports for each patient 1-2 times per week for signs of infection (e.g., antibiotics or intravenous fluids ordered, special orders for wound dressing, orders for isolation precautions) | - Most complete method of case finding  
- May be done prospectively or retrospectively | - Time consuming (requires 10-30 minutes per record)  
- Unable to identify all infections due to:  
  o Missing data, diagnostic reports  
  o Record unavailable at time of review  
  o May be difficult to confirm that criteria for infection have been met | - Additional ICP resources may be required |
| Laboratory reports                | ICP reviews daily laboratory reports for positive culture results that prompt investigation of potential nosocomial infections  
- Significant results ‘flagged’ in electronically-generated batch reports  
- Laboratory staff notify ICP with significant results | - Quickly identifies significant increases in some types of infections  
- Often identifies microorganisms of special concern before any other method (e.g., MRSA)  
- ICPs who visit the laboratory will develop rapport with staff, leading to better cooperation and understanding of each other’s roles | - Infections are missed if cultures are not sent or if microorganisms fail to grow on culture media  
- Infections are missed if diagnosis is based on signs and symptoms alone.  
- False-positive infections if laboratory-based surveillance is used alone (patient may only be colonized e.g., MRSA) | - Electronic laboratory information system beneficial  
- ICPs must work closely with the laboratory that services their hospital to develop reporting mechanisms from the laboratory to the ICP |

**PIDAC: Surveillance of health care-associated infections in patient and resident populations | October, 2011**
B. Electronic Information Systems

Electronic identification of nosocomial infections has the potential benefit of decreasing the amount of time spent on data collection, by limiting the number of cases that would be followed by an ICP to those with a high likelihood of infection. Case finding via computer algorithm may result in more of the ICP’s time being devoted to prevention, rather than to data collection.

As computerized medical information systems become established in hospitals and long-term care homes, the participation of infection prevention and control professionals in the planning stages, when designing the computerized database, will ensure that the necessary structures and fields for electronic screening for nosocomial infections have been included. The following inclusions to the electronic patient record will assist in identifying potential health care-associated infections:

- positive laboratory cultures;
- imaging results;
- details of antibiotic use from the hospital pharmacy; and
- electronic fields indicating whether a patient has an indwelling urinary catheter, a central venous catheter, or is on a ventilator.

While electronic screening of patient/resident records has the potential to increase the efficiency of case finding, caution is advised in the use of this tool. General ‘data mining’ can be an oversensitive tool, resulting in investigation of an excessive number of flagged cases that do not meet the case definitions for infection. Very clear indicators for infection should be incorporated into the search mechanism when setting up a system of electronic screening for infection. For instance, some electronic screening systems for post-discharge surgical site infections have been able to flag cases by placing certain dosage and duration parameters on antibiotics as an indicator for infection in order to separate therapeutic from prophylactic treatments. Incorporation of threshold limits into the electronic screening process is an additional tool that will assist the ICP by indicating when there is an increase above the facility’s baseline rate of infection.

C. Numerator Data Collection in Long-Term Care Settings

What sources of data are available for case finding in long-term care homes?

The wide range of sources of information that are available in acute care to identify infections is not typically available in the long-term care setting (e.g., regular laboratory reporting, nursing Kardex/patient profile). As a result, case finding in long-term care settings will rely more heavily on feedback from those directly involved in resident care.

Sources of data that are commonly used for case finding in the long-term care setting include:

- regular ward visits by the ICP; and
- sentinel surveillance sheets, completed by staff on the wards and collected regularly (these provide an excellent mechanism for feedback from the staff regarding potential infections).
D. Collecting Information for the Denominator

A surveillance rate includes the number of cases (numerator component) developing in the population at risk (denominator component). Therefore, a surveillance system must be able to collect data on the overall population at risk for acquiring health care-associated infections, as well as the individual patients/residents who actually acquire the disease.

For example, for device-associated infections, the population at risk includes the total number of patients/residents exposed to a particular device (e.g., ventilator, central venous catheter, indwelling urinary catheter) during the time period selected for surveillance (e.g., month, quarter). For surgical site infections, the population at risk includes all patients who had the same operative procedure. Additional guidance on rate calculation is provided in Step V, “Calculate and Analyze Surveillance Rates”.

2. Assess the Sensitivity and Specificity of Sources of Surveillance Data

A surveillance program should consider two evaluative criteria applicable to any case finding method: sensitivity and specificity.

a) Sensitivity is the overall proportion of true nosocomial infections that are detected by a case finding method (i.e., the number of true infections occurring in a population divided by the number of infections detected by a case finding method).

b) Specificity of a case finding method describes its ability to correctly exclude infections that are not present (i.e., the proportion of true non-infected patients/residents designated as not having an infection by a case finding method).

Using 2 x 2 Tables to Calculate Sensitivity and Specificity

<table>
<thead>
<tr>
<th></th>
<th>Infection</th>
<th>No infection</th>
</tr>
</thead>
<tbody>
<tr>
<td>Meets case definition</td>
<td>a</td>
<td>b</td>
</tr>
<tr>
<td>Does not meet case definition</td>
<td>c</td>
<td>d</td>
</tr>
</tbody>
</table>

Sensitivity = $\frac{a}{a + c}$  Specificity = $\frac{d}{b + d}$

The following example may be used to illustrate ways to calculate the sensitivity and specificity of a case definition:
**Example:** On a special care unit with 11 ventilated patients, 3 patients have a ventilator-associated pneumonia (VAP). Only two of the three patients meet the case definition for VAP that the ICP has developed, but two patients without a VAP also meet the case definition. The sensitivity and specificity of the case finding method may be illustrated with a 2 x 2 table in this way:

<table>
<thead>
<tr>
<th></th>
<th>VAP</th>
<th>No VAP</th>
</tr>
</thead>
<tbody>
<tr>
<td>Meets case definition</td>
<td>2</td>
<td>2</td>
</tr>
<tr>
<td>Does not meet case definition</td>
<td>1</td>
<td>6</td>
</tr>
</tbody>
</table>

Sensitivity = $\frac{\text{# true positives}}{\text{(# true positives + # false negatives)}} = \frac{2}{3} = 0.67$

Specificity = $\frac{\text{# true negatives}}{\text{(# true negatives + # false positives)}} = \frac{6}{8} = 0.75$

*Figure 2* illustrates a way to demonstrate the assessment of sensitivity and specificity for the above example.
Ideally, a case finding method will have both a high sensitivity and specificity, i.e., it is able to detect a high percentage of all infections, while at the same time identifying only cases with a high likelihood of actual infection. A relatively high specificity is desirable so that the time that an ICP spends confirming an infection is minimized.

Table 3 summarizes the sensitivity and specificity of total chart review relative to other sources of data for case finding. The ICP resources required for each of these case finding methods are also shown in this table. Table 3 demonstrates that similar or higher levels of sensitivity for case detection can be obtained through less resource-intensive case finding methods when compared to total chart review.

Once the data sources that are available to the health care setting have been identified, the sources should be ranked according to their estimated sensitivity (see Table 3). Final selection of data sources to be used for each type of infection that is surveyed will be based on those that have the highest sensitivity and specificity and that are the most feasible to implement in the health care setting.

3. Choose the Most Feasible Surveillance System for the Health Care Setting

The approach to case finding should satisfy all information requirements of the surveillance program, while at the same time be feasible in the context of the infection prevention and control program’s resources.

The surveillance system or approach that will be used in the health care setting must be determined and a decision made as to whether it will be involved in active or passive surveillance.

- **Active surveillance** involves actively seeking out health care-associated infections on a regular basis by individuals trained in surveillance, usually ICPs:
  - ICP seeks out possible health care-associated infections on a regular basis (e.g., several times per week) using a variety of data sources;
  - ICP determines whether an infection meets the criteria for a health care-associated infection based on the standardized case definitions;
  - Requires a high level of ICP effort and resources to be effective.

- **Passive surveillance** involves reliance on staff to provide infection information to the ICP:
  - Patient/resident care staff report infections or suspected infections to the ICP;
  - Requires the least amount of ICP time and resources but is the least sensitive system.

Figure 3 illustrates that the sensitivity associated with active and passive surveillance is directly proportional to the intensity of the surveillance activities involved.

![Figure 3: Intensity of resources associated with active and passive surveillance](image)

Passive surveillance systems may be associated with higher levels of misclassification and underreporting of health care-associated infections because they rely on information provided from staff whose responsibilities are centered on patient/resident care and who are less familiar with the application of case definitions. These staff may not have time to keep abreast of changes in surveillance procedures, surveillance definitions or clues to infection beyond the ward/unit on which they provide care. As a result, passive surveillance systems may not provide high quality data or timely information on changes in the risk of health care-associated infections.
Active surveillance is associated with a higher level of sensitivity and is recommended for case finding. Passive surveillance might, however, be the only feasible approach to case finding due to resource constraints. If this is the case, it is critical that education and training is undertaken for patient/resident care staff to ensure that potential infections are identified and that reporting expectations are met.

**Recommended Best Practice #5:**
Active surveillance is a recommended best practice for surveillance programs in hospitals and long-term care homes because of the higher sensitivity associated with this approach to case finding.

4. **Implement the Data Collection System**

   The range of information source(s) used to screen for nosocomial infections can assist in establishing the thoroughness of a case finding method. Health care settings that draw on a wide range of sources for information will detect a greater number of infections.

   Once the surveillance system has been defined in terms of its case definitions, sources of data and method of data collection, the data that is being received must be “cleaned” or assessed for accuracy and validity. Further investigation of cases that were initially identified as infections requires full chart review and follow-up with patient/resident care staff. This will exclude cases that do not meet the case definition for infection.

   The process for identifying potential infections that require further follow up is illustrated in **Figure 5**.
Boxes 9 and 10 present examples of case finding and data collection in a hospital and a long-term care home.
Box 9: Case Finding and Data Collection (acute care example)

- The ICPs at City General Hospital conduct active surveillance. Each ICP is responsible for undertaking surveillance in a particular patient care area.
- To identify nosocomial infections, the ICPs first undertake a daily review of hospital laboratory reports to identify positive culture results that might indicate infection.
- From this laboratory report, the ICP formulates a list of potential infections in his/her assigned patient care area.
- The ICP then visits the nursing units for follow-up of the positive cultures and for identification of additional potential infections through discussions with unit nurses and notes on patient profiles (‘Kardexes’).
- From these data sources, the ICP develops a full list of potential infections to be confirmed through more detailed chart review and consultation with clinicians.
- The form below assists the ICP in organizing the information collected:

<table>
<thead>
<tr>
<th>Patient ID</th>
<th>Source of data (check all that apply)</th>
<th>Indication of possible infection (e.g., + cultures, fever, antibiotics, new orders for precautions)</th>
<th>Findings from chart review</th>

</tr>
</tbody>
</table>

- For surveillance of device-associated infections (e.g., CVC-associated BSI, ventilator-associated pneumonia), the ICP obtains denominator data (the number of patients exposed to procedures and devices) from the ICU’s specialized database.
- For surgical site infections, denominator data (total number of patients undergoing the selected surgical procedure) is obtained from the City General Hospital’s surgical database.
Box 10: Case Finding and Data Collection (long-term care example)

- At Forest Manor, ward nurses complete a form designed by the ICP during each shift, identifying the patients with signs and symptoms of UTI, skin or soft tissue infections, or of lower respiratory tract infections.

- The total number of patients with indwelling urinary catheters on a ward is also recorded on the form by nursing staff, so that denominator data can be compiled.

- The form shown below is an example that assists the ICP with data collection:

<table>
<thead>
<tr>
<th>Patient ID</th>
<th>Residents in ward showing signs and symptoms of lower respiratory infection? (e.g., fever + malaise, sore throat, cough)</th>
<th>Residents on ward showing signs and symptoms of skin/soft tissue infection? (e.g., pus/drainage from wound site, fever + inflammation or soreness at site)</th>
<th>Resident has an indwelling catheter?</th>
<th>Catheterized residents on ward showing signs and symptoms of urinary tract infections? (e.g., change in character of urine and other symptoms of infection)</th>

- The ICP follows up these residents, discusses them with the ward nurses and applies the pre-established case definitions with laboratory findings in order to classify the case as a confirmed infection, a suspect infection or infection ruled out.

5. Review the Information to Ensure the Dataset is Complete

One of the challenges with any surveillance system is incomplete data reporting. For example:

- surgeons may not realize that they are to report surgical site infections seen in the outpatient clinic;
- staff in an intensive care unit (ICU) may be fully occupied with urgent patient care needs and not complete surveillance forms in a timely fashion.

These challenges generally occur over time, after the initial enthusiasm or novelty of the surveillance system wears off. Methods for regularly reviewing the surveillance system include:
Audits of the surveillance system to ensure that all data items are being collected and that the dataset is complete; and

Assessment of the timeliness of case documentation by calculating the time from onset of infections to the time when they are entered into the surveillance dataset.

Regular reporting of surveillance information back to the providers of the information (e.g., surgeons in their clinics, staff in ICUs) provides feedback, reminds them of the importance of reporting to the system and allows them to see the results of their input and give the infection prevention and control team comments if they do not understand the results.

**Post-discharge surveillance for surgical site infections**

Surveillance for surgical site infections (SSIs) should be a key component of a hospital’s surveillance system given the severity, high cost and frequency of these preventable infections. With a rapidly increasing trend towards shorter stays and an increasing proportion of surgeries performed in an outpatient setting, the frequency of SSIs becoming apparent post-discharge has inevitably increased.

The proportion of SSIs that develop post-discharge has been estimated at around 50% in several studies, but has been reported as high as 84%. An effective surveillance system should include strategies to detect SSIs that develop post-discharge.

Post-discharge surveillance generally involves follow-up with patients or surgeons within a one-month period post-discharge, often via questionnaire or over the telephone, in order to identify potential surgical site infections. However, patient groups have been shown to be unable to recognize SSIs, even when given specific verbal and written instructions. Follow-up both with patients and surgeons for SSIs post-discharge is frequently associated with low response rates. As surgical patients at high risk for infection are less likely to be lost to follow-up, HAIs might appear to be higher than they actually are when results from low risk patients are not included.

To date there is no generally accepted method for conducting post-discharge surveillance for SSIs outside the hospital setting and no formal recommendation on post-discharge surveillance methodology is possible. There is little evidence on which to base recommendations for one particular case finding method for post-discharge SSIs over another. A review of the literature by Kent et al found the following methods to be associated with higher response rates to questionnaires sent to surgeons for information on post-discharge SSIs:

- An enthusiastic and persistent ICP;
- Frequent personal contact by the ICP and other members of the Hospital Epidemiology/Infection Control Committee;
- ‘User-friendly’ data collection sheets (brightly coloured forms with case definitions printed on the back);
- A reliable free courier for pick up and delivery of surgeon’s letters and completed questionnaires;
- Tracking and reminders regarding unreturned questionnaires; and
- Second and third phone calls if the data was not received within the agreed time frame.

Many of these factors require considerable additional time and resources by the Infection Control Team. ICPs are encouraged to develop innovative approaches for the detection of post-discharge SSIs that do not interfere with the time spent on other components of their surveillance system. Examples include:
partnering with organizations providing home care services to surgical patients to ensure that post-discharge SSIs that develop in their clients are promptly reported to the hospital's ICP; electronic screening of patient’s records post-discharge for indications of infection (e.g., return visits to emergency department); and readmission flags on hospital databases to detect admission due to infection.

**CALCULATE AND ANALYZE SURVEILLANCE RATES**

The steps in data collection described to this point have been focused at the level of the individual patient/resident. Calculating incidence rates involves compiling individual level patient/resident data and then aggregating it into a summary of the risk for developing a nosocomial infection within a population of patients over a specified time period.

Incidence rates are population-level measures where the *numerator* is the infection or event of interest and the *denominator* includes the group of persons in which the infection or event may occur during the time frame of interest, i.e., population at risk for nosocomial infection. A summary sheet on the calculation of surveillance rates is provided in Appendix E.

1. **Surveillance Rates Adjusted for Length of Stay**

   In many health care settings, overall HAI rates are calculated by dividing the number of health care-associated infections identified over a given time period (e.g., per month) by the total number of admissions or discharges in the month. However, overall facility HAI rates may be misleading:

   - patients may be at varying risk of infection because of varying length of stay in a facility;
   - the longer a patient is in hospital the greater the likelihood of acquiring infection.

   For example, obstetric ward patients typically have short stays and generally have a lesser risk of developing a HAI. In contrast, ICUs or rehabilitation wards generally have fewer admissions but patients on these wards have longer stays and are at a higher risk of developing a HAI. If the rate of infection was expressed as the number of cases divided by the number of admissions per month, it would likely underestimate the risk of infection on a high turnover, low risk obstetrics ward (because the denominator is inflated) and overestimate it on a low patient turnover, high risk ICU or rehabilitation ward.

   Health care-associated infection rates should be adjusted for length of stay, i.e., the number of infections per patient/resident day, in hospitals and long-term care homes. Rates of infection per patient/resident day, also called *incidence density rates*, provide a more accurate estimate of the risk of infection in a particular health care setting.

<table>
<thead>
<tr>
<th>Incidence Density Infection Rates</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>What are they?</strong></td>
</tr>
<tr>
<td><strong>How are they calculated?</strong></td>
</tr>
<tr>
<td><strong>What information do they convey?</strong></td>
</tr>
</tbody>
</table>
In some areas of long-term care, such as long-term care homes, resident turnover is generally low, particularly in self-care areas. The resident population is generally fixed and the denominator is relatively constant with the same number of residents contributing the same number of resident days. Adjustment for resident length of stay may not be critical in this context.

However, other areas of long-term care, such as units providing Complex Continuing Care (CCC), will have higher numbers of resident transfers and thus a varying denominator.

The total number of resident days over a given surveillance period is often readily available from a facility’s billing department and can be used to calculate a rate of infection expressed in terms of resident days. It is recommended that rates of health care-associated infection be expressed per resident day in order to account for resident transfers in and out of long-term care homes, allowing for more accurate rate comparisons.

**Recommended Best Practice #6:**
It is a recommended practice to adjust rates of health care-associated infection for patient/resident length of stay by using the number of patient/resident days as the denominator, rather than number of admissions or number of beds.

### 2. Surveillance Rates Adjusted for Type of Procedure in the Hospital Setting

Hospital patients are at varying risk for HAIs depending on the therapeutic interventions that they undergo in acute care. For example, patients undergoing knee arthroscopy are at a lesser risk for surgical site infection than those undergoing colon surgery or coronary artery bypass graft (CABG). These differences in infection risk are due to:

- the invasiveness of the procedure; and
- the characteristics of the patients undergoing the procedure.

One way to control for different risks associated with different surgical procedures is to compare patients having undergone the same surgical procedure. The numerator consists of the number of patients having developed a SSI following a specific surgical procedure and the denominator consists of all patients having undergone that same surgical procedure during the same period of time (e.g., in a particular month).

<table>
<thead>
<tr>
<th>Procedure-specific Surgical Site Infection Rates</th>
<th></th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>What are they?</strong></td>
<td>A rate of surgical site infection (SSI) specific to an operative procedure.</td>
</tr>
<tr>
<td><strong>How are they calculated?</strong></td>
<td>By dividing the total number of surgical site infections that occur during a specific time period following a specific operative procedure by the total number of persons undergoing that operative procedure during that same time period.</td>
</tr>
<tr>
<td><strong>What information do they convey?</strong></td>
<td>The risk of SSI associated with a specific type of operative procedure in hospital in a given period of time. The risk of SSI varies according to the operative procedure. Therefore, calculating a rate of infection that is specific to an operative procedure provides a means to control for the varying risks associated with different operative procedures.</td>
</tr>
</tbody>
</table>
NHSN provides a list of operative procedure categories and corresponding ICD-9-CM procedural codes (International Classification of Disease, 9th Revision – Clinical Modification, Volume 3 (Procedures))⁶⁹ that have been developed by the U.S. National Center for Health Statistics (available online at: http://www.cdc.gov/nhsn/PDFs/OperativeProcedures.pdf). These may be used to assist in grouping similar surgical procedures. This list is provided in Appendix F.

Recommended Practice #7:
It is a recommended best practice to calculate rates of surgical site infection in patients undergoing the same surgical procedure. Strategies should also be developed to detect surgical site infections post-discharge. There is no generally accepted method for conducting post-discharge surveillance outside the hospital setting.

3. Surveillance Rates Adjusted for Exposure to Medical Devices

Exposure to medical devices, such as ventilators, CVCs, intravenous catheters, enteral tubes and indwelling urinary catheters, is associated with a higher risk of HAI. The longer a patient/resident is exposed to a device, the greater their likelihood of developing an infection. Adjustment for exposure to medical devices is important in both hospitals and long-term care settings. With a growing population receiving complex continuing care, exposure to medical devices such as CVCs (e.g., for dialysis treatments, supportive care) is increasing outside of the hospital setting. In addition, the proportion of long-term care residents with indwelling urinary catheters can exceed 10%.

To obtain a rate that is adjusted for length of exposure to a device, divide the number of device-associated infections by the total number of days that all patients/residents were exposed to the device during the surveillance period. For example:

- A surveillance program monitoring ventilator-associated pneumonias (VAPs) among ICU patients would calculate the rate of infection by dividing the number of VAPs in ICU patients by the total number of days during which ICU patients were ventilated during the surveillance period (e.g., month).
- The complex continuing care unit of a long-term care home monitoring central venous catheter-associated bloodstream infections would divide the number of primary bloodstream infections in CCC patients/residents by the total number of days during which CCC patients/residents had a CVC in place during the surveillance period (e.g., quarter).

</tr>
</tbody>
</table>
Recommended Practice #8:
It is a recommended best practice to calculate rates of device-associated infection that are adjusted for duration of exposure to the device.

Denominator data for device-associated infections

Obtaining data on the total number of patients/residents at risk for device-associated infection may present a challenge for some health care settings. In some hospitals, special care areas (e.g., the ICU) may maintain their own database on patients where the number of days that a particular patient was exposed to a device is included or can be included as part of data collection. Where device-days are not routinely collected within a patient/resident population, surveillance systems can develop other means for obtaining this data.

What tools can be used for collecting denominator data for device-associated infection rates?

Some hospitals and long-term care homes have arranged for health care providers to complete an index card outlining the date that a patient started on a device and the date that this exposure ended. These completed cards can be routinely picked up by the ICP.

Figure 6 illustrates a sample card that may be used by staff for the collection of device-days for CVC- associated bloodstream infection rates.

What tools can be used for collecting denominator data for device-associated infection rates?

Another method for collecting information about device-days is to have staff count the total number of patients/residents who are exposed to the device of interest each day and report these figures to the ICP. While this approach will provide the total number of device-days required for the denominator, it does not provide information on how long each patient/resident was exposed to a device.

For example, if the ICP is surveying the rate of UTIs associated with indwelling catheters among those over age 65, only the total number of catheter-days will be available using this method of data collection. The number of catheter-days in the over 65 age group cannot be separated from this total for use in the denominator; hence the rate in this age group cannot be calculated. Obtaining the length of time that each patient/resident is exposed to a particular device, rather than the total number of device-days for a patient care area, is ideally recommended as part of data collection for calculating device-associated infection rates.

Figure 6: Sample card for collection of device-days for CVC-associated BSI denominator

**Recommended Practice #9:**
When collecting data for the denominator for device-associated infection rates, it is a recommended best practice to collect data on the length of time that each patient/resident was exposed to a particular device, rather than the total number of days that all patients were exposed to the device.

Boxes 11 to 14 provide example data sets and calculation of incidence HAI rates for AROs and HAI rates adjusted for exposure to procedures and devices in the fictional hospital and long-term care home.
**Box 11: Calculation of Incidence of Device-associated Infection (acute care example)**

The Infection Control Team at City General Hospital calculates the following infection rates over the quarterly surveillance period. The ICP obtains data on exposure to central lines and ventilators for each patient from the ICU database. These data are demonstrated in the following spreadsheet:

<table>
<thead>
<tr>
<th>Patient ID</th>
<th>Date of central line insertion</th>
<th>Date of central line removal</th>
<th>Date of primary bloodstream infection</th>
<th># of days with central line</th>
<th>Date patient went on ventilator</th>
<th>Date patient was taken off ventilator</th>
<th>Date of onset of pneumonia</th>
<th># days on ventilator</th>

</tr>
</tbody>
</table>

Total for first quarter: 8 infections 1080 line days 4 total infections 660 ventilator days

In order to calculate the rates of central-line associated bloodstream infections and ventilator associated pneumonias, the ICP totals the columns in the spreadsheet above and divides the number of infections by the total number of device days. Rates of nosocomial infection during the surveillance period are shown below:

<table>
<thead>
<tr>
<th>Infection outcome</th>
<th>Number of events (numerator data)</th>
<th>Population at risk (denominator data)</th>
<th>Rate of infection</th>
</tr>
</thead>
<tbody>
<tr>
<td>Central line- associated bloodstream infection</td>
<td>Primary bloodstream infections among ICU patients on central lines: 8</td>
<td>Total number of days that ICU patients were on central lines over year period: 1080</td>
<td>Rate of bloodstream infection: 8 / 1080 X 1000 = 7.4 per 1000 patient central line days</td>
</tr>
<tr>
<td>Ventilator-associated pneumonia</td>
<td>Pneumonias developing in ventilated patients: 4</td>
<td>Total number of days that ICU patients were on ventilators: 660</td>
<td>Rate of pneumonia: 4 / 660 X 1000 = 6.1 per 1000 patient ventilator days</td>
</tr>
</tbody>
</table>
Box 12: Calculation of Incidence of Surgical Site Infection (acute care example)

- The ICP calculates the rates of surgical site infections:
  - The numerator is obtained by totalling the number of surgical site infections following a particular operative procedure.
  - The denominator is obtained by totalling the number of patients having undergone that particular procedure over the quarterly surveillance period, obtained from the hospital’s surgical database.
  - Rates of surgical site infection are presented per 100 procedures in the table below:

<table>
<thead>
<tr>
<th>Type of surgery</th>
<th>Number of surgical site infections following surgery</th>
<th>Number of patients undergoing surgical procedure per quarter</th>
<th>Rate of infection (No. infections per 100 procedures)</th>
</tr>
</thead>

</tr>
<tr>
<td>Abdominal hysterectomy</td>
<td>4</td>
<td>91</td>
<td>4.4 per 100 procedures</td>
</tr>
</tbody>
</table>

4. How Often are Surveillance Rates Calculated?

For closer monitoring of changes to the risk of acquiring HAIs, many health care settings will calculate rates of nosocomial infections on a monthly basis. It is common practice to calculate HAI rates monthly and summarize and present surveillance data quarterly to facility committees, patient/resident care staff and other stakeholders.

For example, calculating MRSA infection rates on a monthly basis will allow the Infection Control Team to track these microorganisms and respond to the changing risk of infection in a timely manner. Some special care areas, such as ICUs, may also calculate rates of device-associated infections on a monthly basis for faster response to clusters of infection among its highly susceptible patient group.
Box 13: Example Calculation of Incidence of Antibiotic-resistant Organisms (AROs)

- For the numerator, the ICPs total the number of persons both colonized and infected with MRSA and/or VRE.
- As all patients are at risk for colonization or infection with MRSA and/or VRE, the denominator for this rate consists of the total number of patient days among those admitted to hospital during the surveillance period.
- Monthly rates of colonization and infection are calculated in addition to quarterly rates, in order to detect increases that will require immediate intervention. The ICPs obtain the number of days that all patients spent in hospital from the hospital’s administrative database and totals this to obtain the denominator for both the monthly and quarterly surveillance rates:

<table>
<thead>
<tr>
<th>Patient ID</th>
<th>Admission date</th>
<th>Discharge date</th>
<th>MSRA cultures</th>
<th>VRE cultures</th>
<th>Number of days in hospital</th>
</tr>

<td><strong>112</strong></td>
<td><strong>140,000</strong></td>
<td><strong>8.0 \text{ per 10,000 patient days}</strong></td>
</tr>
</tbody>
</table>

<table>
<thead>
<tr>
<th>VRE</th>
<th>No. of laboratory-confirmed cases of VRE</th>
<th>Total no. of patient days in hospital</th>
<th>Rate of infection</th>
</tr>
</thead>
<tbody>
<tr>
<td>January</td>
<td>19</td>
<td>45,000</td>
<td>4.2 \text{ per 10,000 patient days}</td>
</tr>
<tr>
<td>February</td>
<td>25</td>
<td>48,500</td>
<td>5.2 \text{ per 10,000 patient days}</td>
</tr>
<tr>
<td>March</td>
<td>21</td>
<td>46,500</td>
<td>4.5 \text{ per 10,000 patient days}</td>
</tr>
<tr>
<td><strong>Total for 1st quarter</strong></td>
<td><strong>65</strong></td>
<td><strong>140,000</strong></td>
<td><strong>4.6 \text{ per 10,000 patient days}</strong></td>
</tr>
</tbody>
</table>

- The rates expressed in the table above are per 10,000 patient days. The infrequency of MRSA and VRE colonization or infection relative to the total number of days that patients spent in a hospital/long-term care home makes the infection rate expressed per 10,000 patient days more appropriate. Hospitals and long-term care homes should present their rates using the same denominator as that of other health care settings or national benchmarks to which they wish to compare.
Box 14: Calculation of Incidence of Nosocomial Infections (long-term care example)

Example #1: Urinary Catheter-associated UTIs

- The ICP at Forest Manor collects data on the use of indwelling urinary catheters from the forms completed by ward nurses.
- The ICP inputs data from the forms into an electronic spreadsheet and totals the number of catheter days in the resident population and the total number of UTIs in this group:

<table>
<thead>
<tr>
<th>Resident ID</th>
<th>Date of catheter insertion</th>
<th>Date of catheter removal</th>
<th>Date of UTI</th>
<th># Catheter days</th>

<td>.</td>
<td>.</td>
</tr>
<tr>
<td>0100</td>
<td>March 7</td>
<td>March 31</td>
<td>March 31</td>
<td>24</td>
</tr>
</tbody>
</table>

Total for first quarter: 7 infections 1790 catheter days

- There were 1790 indwelling catheter days at Forest Manor over the quarterly surveillance period and 7 symptomatic urinary tract infections among residents with indwelling catheters. The rate of catheter-associated UTIs is:

\[
\frac{7 \text{ UTIs in residents with indwelling catheters}}{1790 \text{ resident catheter days}} \times 1000 = 3.9 \text{ UTIs per 1000 resident catheter days}
\]

Example #2: Lower Respiratory Infections

- The population at risk for lower respiratory tract infections includes all residents at Forest Manor.
- Sixty-one lower respiratory tract infections were identified over the quarterly surveillance period.
- As all residents at Forest Manor are at risk for respiratory tract infections, the denominator for this rate is the total number of resident days.
- Forest Manor’s billing database indicates that there were 16,940 resident days over the quarterly surveillance period. The rate of nosocomial infection is:

\[
\frac{61 \text{ lower respirator tract infections}}{16940 \text{ resident days}} \times 1000 = 3.6 \text{ infections per 1000 resident days}
\]

Recommended Practice #10:

Health care settings should use electronic systems to store data and assist with the calculation of HAI rates.
5. **Assignment of Nosocomial Infections to Specific Surveillance Periods**

Infections are typically associated with the date of onset of symptoms. However, in certain cases, infections identified in the current surveillance period may have resulted from an exposure that took place in the previous surveillance period. This is particularly true for SSIs related to joint surgery, where an infection can take up to one year to develop. Case definitions for health care-associated infections should take these factors into account.

6. **How to Organize Data in Electronic Format for Calculation of Rates**

The examples in Boxes 11 to 14 show the calculation of HAI rates from data compiled in an electronic spreadsheet/database. It is a recommended practice that all health care settings have a computerized system to track and monitor patient/resident surveillance data. This system should also allow for the analysis of infection data or, at a minimum, allow the data to be exported to statistical analysis software.

Where electronic systems are used to store and analyze data, HAI rates can be calculated with greater ease and efficiency and are less prone to error, provided that the ICP has received training in the use of such programs. Health care settings that do not use specific infection control computer programs should track infections using a spreadsheet or database program. Several simple statistical software packages compatible with most spreadsheet/database programs are currently available. ICPs requiring assistance in setting up an electronic system may be able to contact their facility’s information technology staff, local public health unit or Regional Infection Control Network (RICN) for guidance.

7. **How to Handle Missing Data**

Occasionally a hospital or long-term care home will encounter missing data in the calculation of their HAI rates. Missing data are common when doing post-discharge surveillance for SSIs, as many patients are lost to follow-up and their infection status will be unknown. There are several ways to deal with surveillance results when some of the data are not available:

- If it is unknown whether a patient/resident developed an infection then this person should be excluded from both the numerator and the denominator in rate calculations.
- As a general rule, if the number of patients at risk for an infection excluded from a rate exceeds 20% because of missing data, then the validity of the rate may be jeopardized.
- The rate should be reported with the caveat that “over X% of patients at risk were excluded from the rate due to missing observations”.
- Hospitals and long-term care homes should keep track of the type of data that is most frequently missing and enhance efforts to ensure the completeness of the data.

**APPLY RISK STRATIFICATION METHODOLOGY**

Patients/residents served by differing health care settings have differing extrinsic risk factors, related to the treatments and procedures that they undergo, and intrinsic (or patient-related) risk factors for HAI, including underlying disease condition and advanced age. Without adjustment for these factors, comparisons within the same health care setting or inter-facility comparisons may be invalid or misleading.

For example, comparison of rates of infection between a community hospital and a tertiary care hospital may show a substantially higher rate of HAI in the tertiary care hospital. This difference may be due to several factors:
higher degree of susceptibility to nosocomial infection in the more acutely ill population served by the tertiary care hospital; the number of health care workers in direct contact with the patient; and the greater invasiveness of procedures undertaken in the tertiary care setting. Hence, comparisons between these two hospitals will not be meaningful as the infection risks are very different.

1. **Risk Stratification**

Stratification is a process to control for differences in the underlying risk factors for infection. Risk stratification involves categorizing patients/residents with similar susceptibilities to infection and calculating the HAI rates based on these groupings. Risk stratification allows for meaningful comparison of rates among patients/residents with similar risks within a health care setting or between health care settings and at different points in time.\(^2\)

**Risk stratification in long-term care**

Risk stratification of HAIs in long-term care is uncommon, but may provide useful information. For instance, it is recognized that long-term care residents with limited mobility and who require assistance with daily living are at higher risk of lower respiratory tract infection. It is possible that resident mobility could be developed as an indicator of risk of health care-associated respiratory infection in the long-term care setting.

**Risk stratification in acute care**

Risk stratification methodology is generally applied to surgical site infections and, occasionally, to other types of infections (e.g., neonatal infection rates stratified by birth weight). Rates of health care-associated infection are often stratified by the major non-modifiable risk factors pertaining to that infection.

Surgeries can be classified by wound class, i.e., the likelihood of contamination of the surgical site at the time of the operative procedure:

- Surgical procedures falling into the clean wound class category (class I) are non-emergency, involve access only to the sterile body sites and carry the lowest risk of surgical site infection.\(^6\)
- Procedures falling into the contaminated wound class (class III) carry a high risk of infection often because they involve unusual contamination from a non-sterile site (e.g., large bowel resection contaminated with faecal material).

Wound class is often determined by the nature and urgency of the procedure and is not modifiable by changes to infection prevention and control practices. Therefore, stratification of infection rates by wound class allows for the comparison of SSI among procedures that carry similar risks.

Refer to Appendix G for a description of wound classes.

**Recommended Practice #11:**

It is a recommended best practice that hospitals stratify rates of procedure-specific surgical site infections by wound class.
2. Using Risk Indices in Stratification

Risk indices are used to combine several risk factors for a particular infection, rather than calculating a separate rate for each of these factors. In selecting a risk index, the ICP should use categories of risk that have been validated for predicting the risk of infection.

Limited progress has been made in developing practical risk indices that have been shown to correlate well with the risk of nosocomial infection. One example, the Acute Physiologic and Chronic Health Evaluation (APACHE II) is a scoring system used to establish severity of illness among ICU patients, which is thought to correlate with the risk of acquiring a nosocomial infection. However, the APACHE system has had limited utility in predicting risk of nosocomial infection because the patients with the highest scores generally do not survive long enough to acquire a HAI. Where a risk index has not been shown to correlate with the actual risk of infection in a health care setting, it will be of little use.

The NHSN risk index for SSIs

The U.S. NHSN system has developed a risk index specifically for surgical site infections, based on a combination of patient and procedure-related risk factors. The risk factors included in the NHSN index are non-modifiable and relate to both the patient and the characteristics of the procedure. The risk index components include:

- length of the operative procedure;
- wound class; and
- the American Society for Anesthesiologists (ASA) score, which summarizes the extent of underlying illness and functional limitations of a patient.

In this risk index, all patients receive a score from 0 to 3 based on the following characteristics of the patient and the surgery:

<table>
<thead>
<tr>
<th>Wound class score ≥ 3</th>
<th>1 point</th>
</tr>
</thead>
<tbody>
<tr>
<td>ASA score 3,4,5</td>
<td>1 point</td>
</tr>
<tr>
<td>Length of operative procedure beyond 75th percentile cut-off for that procedure</td>
<td>1 point</td>
</tr>
</tbody>
</table>

The NHSN risk index score is commonly used as a basis for stratification for SSIs and has the advantage of facilitating comparability of rates of infection with other hospitals, adjusting for risk through the use of this index. The index components (i.e., wound class, ASA score, length of operative procedure) are also easily obtainable from a hospital's surgical database information.

Figure 6 illustrates a sample chart abstraction tool for all patients undergoing cardiovascular surgeries that can be used to gather key data on SSIs and other risk factors for use in the NHSN index. A hospital may find this tool useful when the information cannot be obtained directly from a health care facility's surgical database.

Pearl of Wisdom: The information required for risk stratification (e.g., wound class, length of procedure) needs to be collected from both the patients developing infections and the patient population at risk.
PIDAC: Surveillance of health care-associated infections in patient and resident populations | October, 2011

[Adapted from: Sunnybrook Health Sciences Centre, Toronto, Ontario]

Figure 7: Sample cardiovascular surgical site infection chart abstraction tool

While the NHSN index is the most widely-used for health care-associated infections, several investigators have shown that it was unable to accurately predict the risk of infection across a wide range of surgical procedures. Some health care settings may find the NHSN SSI risk index useful because it allows them to compare their rates of infection with other...
hospitals also using this index. However, its ability to adjust for the true risk of surgical site infection should be recognized.

Box 15 provides an example of calculating risk stratification based on wound class in a fictional hospital.

INTERPRET INFECTION RATES

Infection Control Professionals must be able to interpret HAI rates so that they can identify areas where improvements to infection prevention and control practices are needed to lower the rate of infection, or to evaluate where preventive interventions have been effective in reducing the risk of infection. Interpreting the meaning of a rate of infection requires a close working knowledge of how one’s surveillance system operates and of the changing risks of infection in one’s facility. The recommended steps in interpretation of surveillance rates are summarized in Figure 7.

A hospital or long-term care home should use the following questions to guide the interpretation of a surveillance rate:

1. **Are the rates accurate?**
   As a first step in interpretation of an infection rate, the ICP should ask: *have the rates been accurately calculated?*
   
   - It is recommended that all HAI rate calculations be pre-programmed into your computerized system or spreadsheet/database. Calculation of surveillance rates through a computerized system will eliminate some of the potential for the miscalculation of rates and save valuable ICP time.
   
   - It is also recommended that another member of the Infection Control Team review, and if necessary re-calculate, the rates using your infection data. If discrepancies in the rates are found, then identification of the area of miscalculation can serve to reinforce methods and provide additional practice in calculation of rates.

   **Recommended Practice #12:**
   It is a recommended best practice to have a colleague review HAI rates and check their accuracy prior to any interpretation of the rate.

2. **Are there any major deviations from previous data? Do the rates make sense?**
   At this point, the ICP will notice if a rate deviates substantially from previous surveillance periods. ICPs may substantiate this statistically through the use of a standard deviation.
Box 15: Application of Risk Stratification Methodology (acute care example)

- The Infection Control Team at City General Hospital stratifies its rates of surgical site infections for cholecystectomy and colectomy by wound class.
- The team obtains information on wound class for each patient undergoing cholecystectomy and colectomy over the quarterly surveillance period from the hospital’s surgical database:

<table>
<thead>
<tr>
<th>Patient ID</th>
<th>SSI</th>
<th>Wound class</th>
</tr>
</thead>
<tbody>
<tr>
<td>Colectomy</td>
<td></td>
<td></td>
</tr>
<tr>
<td>0001</td>
<td>No</td>
<td>II</td>
</tr>
<tr>
<td>0002</td>
<td>No</td>
<td>II</td>
</tr>
<tr>
<td>0003</td>
<td>Yes</td>
<td>III</td>
</tr>
<tr>
<td>0250</td>
<td>No</td>
<td>III</td>
</tr>
<tr>
<td>Total</td>
<td>10 infected/ 250 total</td>
<td></td>
</tr>
<tr>
<td>Cholecystectomy</td>
<td></td>
<td></td>
</tr>
<tr>
<td>0001</td>
<td>No</td>
<td>I</td>
</tr>
<tr>
<td>0002</td>
<td>Yes</td>
<td>I</td>
</tr>
<tr>
<td>0003</td>
<td>No</td>
<td>II</td>
</tr>
<tr>
<td>0300</td>
<td>Yes</td>
<td>III</td>
</tr>
<tr>
<td>Total</td>
<td>11 infected/300 total</td>
<td></td>
</tr>
</tbody>
</table>

- The infection control team totals the number of patients in each wound class and calculates the following rates:

<table>
<thead>
<tr>
<th>Surgical Site Infections</th>
<th>Surgical site infections following surgery</th>
<th>Total number of patients undergoing surgical procedure over quarter</th>
<th>Rate of infection (No. infections per 100 procedures)</th>
</tr>
</thead>
<tbody>
<tr>
<td>Colectomy</td>
<td>10</td>
<td>250</td>
<td>( \frac{10}{250} \times 100 = 4.0 \text{ per 100 procedures} )</td>
</tr>
<tr>
<td>Wound class I-II</td>
<td>4</td>
<td>190</td>
<td>2.1 per 100 procedures</td>
</tr>
<tr>
<td>Wound class ≥ 3</td>
<td>6</td>
<td>60</td>
<td>10 per 100 procedures</td>
</tr>
<tr>
<td>Cholecystectomy</td>
<td>11</td>
<td>300</td>
<td>3.7 per 100 procedures</td>
</tr>
<tr>
<td>Wound class I-II</td>
<td>5</td>
<td>250</td>
<td>2.0 per 100 procedures</td>
</tr>
<tr>
<td>Wound class ≥ 3</td>
<td>6</td>
<td>50</td>
<td>12.0 per 100 procedures</td>
</tr>
</tbody>
</table>
Using standard deviation to assess data

The standard deviation (SD) of a rate of infection indicates the average variation around the mean rate, i.e., data values will lie somewhere above or below the average that has been calculated from all of the values. A rate that is farther than 2 SDs from the mean rate of infection represents an unusual occurrence. The Infection Control Team could seek the assistance of a biostatistician/epidemiologist in calculating the mean rate and standard deviation to assist them in interpreting whether a difference is substantial. See Box 16 for a graphical illustration of how the standard deviation may be used to guide action when HAI rates appear to be elevated.
Box 16: Use of Standard Deviation to Guide Decision-making Related to Increases in HAI Rates

- **Using standard deviation (SD) calculated from HAI rates, it can be seen from the graph below that 95.5% of HAI rates will fall within ±2 SD of the mean rate. This can be used to determine, on a month-to-month or quarterly basis, whether a particular infection rate is acceptable or is abnormally high.**

- **For example, after generating monthly rates for MRSA colonization in Forest Manor, at the end of a year the ICP calculates a mean rate of 2 cases per 1,000 resident days.**
  - Using the rates from the previous 12 months to calculate the standard deviation results in a standard deviation of 1.
  - This means that, in any given month, 68.2% of rates will be between 1 and 3 cases per 1,000 resident days (mean ± 1 SD) and 95.5% of rates will be between 0 and 4 cases per 1,000 resident days (mean ± 2 SD).
  - If ±2 SD is considered acceptable, then only months where the rate was above 4 cases per 1,000 resident days would require investigation.

**Using critical thinking to assess data**

If no errors are detected in the calculation of a rate and the rate is substantially higher or lower than expected, then the ICP should ask: *do these rates make sense?*

The ICPs’ day-to-day activities in case finding provide them with a general idea of the range of frequencies of various types of infections that can be expected in their facility. The ICP
can apply this working knowledge to assess whether a particular rate of infection seems reasonable, based on what they have observed in their facility over the surveillance period.

Unusually high HAI rates that signify a cluster or outbreak would normally come to the attention of the ICP before HAI rates are calculated. If an unusually high rate of infection indicates an outbreak, then the ICP should bring this to the immediate attention of the Infection Control Team and implement their outbreak management protocols if required.

Substantial deviations in HAI rate from previous surveillance periods that are not explained by an outbreak situation should be investigated by the ICP and Infection Control Team. These differences could indicate:
- changes in hospital practices;
- changes in surveillance methodology; or
- changes to case definitions.

### Box 17: Example of How Changes to Hospital Practices Appear to Affect the Infection Rate

The following demonstrates how changes in facility practices in one community hospital impacted case finding for surveillance and resulted in an apparent decrease in the rates of MRSA infection over time:

*The Infection Control Team at this hospital was elated when the proportion of S. aureus isolates that were resistant to methicillin decreased from 34% to 0% in one surveillance month. Upon further investigation, it was found that two changes in the hospital, unrelated to the risk of MRSA, were responsible for this change. First, surgeons had begun to treat potentially infected wounds based solely on signs and symptoms. Second, the hospital laboratory began screening wound specimens and selected a limited set, meeting specific criteria, for culture. Together these changes reduced the total number of S. aureus isolates that were available for testing for methicillin resistance, including those that were positive. The observed reduction in MRSA infections were attributed to these facility changes, impacting the sensitivity of case finding, rather than to any changes in infection prevention and control practice.*

*Pottinger JM, Handbook for Hospital Epidemiologists 1998*

Additional examples of changes to hospital practices and the apparent change to the rates of nosocomial infection that can result from these changes are provided in Table 4.

**Recommended Practice #13:**
Explore the possibility that differences in rates of infection in your facility from previous surveillance periods may be the result of institutional practices or surveillance practices.
Table 4: Examples of Practices that Affect Observed Infection Rates

<table>
<thead>
<tr>
<th>Change in Practice</th>
<th>Apparent Effect on Infection Rate</th>
</tr>
</thead>
</table>
| Increasing proportion of treatment taking place in outpatient setting rather than in hospital | Decrease in overall infection rate, because surveillance is rarely performed in the outpatient setting  
OR  
Increase in infection rate if low-risk procedures are performed in the outpatient setting and those taking place in hospital are among high-risk surgical patients |
| Length of stay in hospital following treatment is decreased                          | Decrease in overall rate of infection because fewer infections are detected post-discharge  
OR  
Increase in infection rate as patients staying in hospital are more severely ill and at a greater risk of infection |
| Patients residing in lodging house or boarding unit of hospital are not counted as admitted patients; thus, these patients are not included in the denominator | Increased infection rate if surveillance is conducted on these units, especially if outbreaks of infections on these units (e.g., C. difficile, gastroenteritis) are detected |
| Automated IT services office associates surgical procedure to admitting physician, regardless of physician’s specialty, rather than to the surgeon performing the procedure | Inaccurate surgeon-specific infection rates, because some surgical site infections will be assigned to the wrong surgeon |
| Physicians treat patients based on signs and symptoms of infection, without obtaining cultures | Decreased rate of infection if case finding relies solely on microbiology reports |
| Microbiology laboratory changes screening criteria for processing specimens          | Decreased rate of infection if case finding methods rely on laboratory reports |
| Definitions inconsistently used or inconsistently applied                            | Inaccurate infection rates |

[Adapted from: Haley et al, 1980\textsuperscript{77}]

**Temporal variations impacting on data**

Rates of infection may vary from previous surveillance periods due to changes related to time:

- seasonal variations - for example, respiratory infections have a low frequency in the summer months but may increase over the winter months;
- weekly variations - for example, onset of infection over the weekend may not be recognized or confirmed until Monday when patient/resident care and laboratory
staffing levels increase, which may result in a higher number of infections being recorded on that day.

These contextual factors should also be considered in interpretation of a surveillance rate. If a health care setting is doing seasonal surveillance (e.g., influenza surveillance), the same time period must be used each year when doing trend comparisons.

3. Rate Comparison to Benchmarks

It is recommended that health care settings compare their HAI rates against benchmarks, both internal and external. There are three common rate comparisons that may be used:

1. **Recognized standards or benchmarks.** A hospital or long-term care home can evaluate their rates of infection relative to an established benchmark. For example, the U.S. NHSN system publishes reports that present rates of HAIs compiled from 211 participating hospitals.\(^{78,79}\) HAI rates are presented with both a mean rate and percentiles, which range from 10% to 90%. ICPs may use these benchmarks if their surveillance data have been collected in the same way as the NHSN data.

   For some infections there are recognized rate standards. For example, the mean rate of infection for clean laminectomies is 0.88%.\(^{78}\) For other infections, there are no well-established benchmarks, and a group of similar health care settings may choose to benchmark against each other

2. **Rates from previous surveillance periods.** Depending on the infection of interest, health care settings should choose to compare their HAI rates to those calculated in previous surveillance periods (e.g., previous month, previous quarter, previous year) to detect changes in the risk of infection or deviations from a baseline rate, or to evaluate the effectiveness of interventions that have been implemented.

3. **Benchmarks set by one’s own facility.** In a well established, ongoing surveillance system, the Infection Control Team will have a good idea of its baseline HAI rates, which may be lower than external benchmarks. In such cases, the hospital or long-term-care home may set their own goals for HAI rates based on what can be achieved in their facility and compare rates of infection to their own internal benchmarks.

In comparing HAI rates to those of other hospitals or long-term care homes, an ICP should review the surveillance methods used by these facilities. This review can assist in identifying whether differences in the rates of infection can be attributed to surveillance methods, such as different approaches to case finding, or to the use of different case definitions. Upon review of the surveillance methods of several other facilities, a health care setting should be able identify a those that use the same case definitions and similar approaches to case finding. This set of peer facilities can provide an ongoing comparison group of surveillance rates.

If the ICP suspects that there is a meaningful difference in their rate of infection relative to other facilities or to previous surveillance periods, then consultation with an epidemiologist or biostatistician can assist in determining whether any differences in the risk of infection are statistically significant. Some facilities may have this expertise available, while others may have to seek out someone with this training. The local public health unit is a good source of expertise. Another source of assistance in interpretation of surveillance rates is the Department of Epidemiology/Biostatistics of a nearby university.
Pearl of Wisdom: Comparisons over time or across health care settings are only appropriate if the same case finding methods have similar sensitivities and specificities, the same case definitions are applied to establish infection and the same methods are used to calculate rates of infection and to adjust for risk factors.

Recommended Practice #14:
Identify a set of peer institutions that use the same case definitions and similar case finding methods to serve as a comparison group. When comparing HAI rates to those of other hospitals or long-term care homes, an ICP should consider the surveillance methods used by these facilities.

Effects of sample size
While HAI rates may be accurately and consistently calculated over time, they may not be meaningful if the number of events (i.e., denominator) is too small. For example, in the sample dataset shown in Box 12, there were only two reported SSIs following Laminectomy over the course of a year. A single increase in the number of laminectomy-associated SSIs (i.e., from two to three cases) would result in a 50% increase in the SSI rate (assuming the denominator, or number of procedures, remained constant).

ICPs should consider the number of events on which a rate is based when interpreting surveillance rates. A low number of events results in instability in rates of nosocomial infection. An epidemiologist/biostatistician can assist in confirming whether there are too few infection events for statistically meaningful differences to be detected.

4. Investigation of Increased HAI Rates
If the Infection Control Team determines that an increased HAI rate reflects a difference in the true rate of infection, then investigation of the cause of the increased rate is required. The ‘Chain of Transmission’ model provides a useful framework to guide this investigation.

This model, illustrated in Figure 8, summarizes all components necessary to the process of infection, using MRSA as an example:

- MRSA is present in the community and hospital;
- an elderly, immunocompromised patient with frequent hospitalizations may act as a reservoir in the hospital setting;
- the mode of transmission is from person-to-person;
- the hands of health care providers may serve as the vector for transmission, transferring MRSA bacteria from the colonized patient to the surgical wound of the patient’s roommate;
- the portal for entry in the roommate is the surgical site;
- whether or not this exposure to MRSA results in a surgical site infection depends on the individual’s susceptibility to infection.

Increases in HAI rates are not necessarily a reflection of a failure in patient/resident care or of facility practice. Differences in the rate of infection arise from many factors, including:
- factors relating to the infectious agent, such as increased frequency of the microorganism in the hospital or community setting; and
- factors relating to the host, including an increasingly acutely ill and susceptible patient population in health care settings.

The *Chain of Transmission* model may be useful in identifying areas where the infection process can be interrupted through changes to infection prevention and control practices. The model also useful when explaining changes in the epidemiology of nosocomial infections.

Using the example in Figure 8, reductions in the rate of MRSA infections may be achieved through enhanced infection prevention and control practices, such as screening patients on admission and the use of Additional Precautions for those colonized with MRSA (to interrupt transmission) or improved hand hygiene in patient care staff.

**Recommended Practice #15:**
If the Infection Control Team finds that an elevated HAI rate represents an increased risk of infection, it is a recommended practice to use a conceptual framework (such as the *Chain of Transmission* model) to suggest explanations for these rates and areas where improvements to infection control practices could reduce the rates.

*Figure 9: Chain of Transmission example: MRSA*
5. **Discuss Interpretation with the Infection Control Team**

Once the ICP has confidence in his/her interpretation of the HAI rate, it is important to share this with others on the Infection Control Team. Where a higher rate of infection is thought to reflect a greater risk of infection, this interpretation should form the basis for development of improved infection prevention and control practices. After an infection prevention and control program has been developed and implemented with patient/resident care staff, the eventual re-calculation of rates as part of a formal evaluation exercise would be used to assess the effectiveness this program, as demonstrated in the continuous feedback loop in Figure 1.

If the ICP is of the opinion that differences in rates of infection are due to small sample size or to changes in surveillance methods, then he/she should report this interpretation. For example:

- An ICP might report a higher rate of SSIs over a particular surveillance period, while noting that the difference in rate was only due to one additional infection event over that period and that this rate of infection is not likely to be reflective of any changes in the risk for that particular infection.
- An ICP in a long-term care home might report a higher rate of urinary catheter-associated UTIs relative to other facilities in the region, with an explanation that their facility uses a case definition for UTIs that includes only positive culture results, whereas the other facilities use both clinical criteria and laboratory results to establish infections.

**COMMUNICATE AND USE SURVEILLANCE INFORMATION TO IMPROVE PRACTICE**

If surveillance data are not used to effect changes to infection prevention and control practices, then the surveillance system is not working. Communication of surveillance data and their use as an input to infection prevention and control practice constitutes the end goal of an effective surveillance system. A surveillance system that simply collects and houses data without communicating it to stakeholders stops short of attaining the main goal, that of improved infection prevention and control practice and decreased rates of HAIs.

1. **Communication at the Health Care Setting Level**

Communication of HAI rates takes place first at the health care facility level, often to a hospital or long-term care home’s infection prevention and control committee. This type of communication provides a global view of the risk of HAIs in the health care setting over a specified period of time. This communication, often in the form of a quarterly report, should outline any changes to the risk of infection across all patient/resident care areas that are covered by the surveillance system.

To assist clinicians and health care administrators to understand the interpretation of HAI rates, it is important to describe where this rate is situated relative to previous surveillance intervals or in relation to like facilities. For example, reporting a rate of 5.6 CVC-associated bloodstream infections per 1000 patient days may have little meaning to a hospital committee without knowledge as to what this rate signifies. Comparing this rate to a mean rate of infection available from a group of comparator facilities or an established benchmark rate and presenting this graphically with the facility’s data are useful (refer to bar graph in Appendix H).

2. **Communication Targeted to a Specific Area of Patient/Resident Care**

Communication of HAI rates should also be targeted to specific patient care areas or specialty services that have participated in the data collection, such as ICUs or surgical units in hospitals, or complex continuing care units in long-term care homes. These reports offer
a more detailed analysis of the specific types of infections affecting patients/residents served by these particular care areas.

Information is generally presented as a written report. The targeted report may be distributed at a regular program committee meeting or could be used in a workshop, for example, which might comprise managers, health care providers and the ICP or Infection Control Team. The information provided in this report may serve as a basis for discussion between the ICPs and the program’s staff on emerging concerns in patient safety, reasons for changes in their rates of infection, or the effectiveness of specific infection prevention and control practices and interventions.

The information provided in surveillance reports can also be used to direct resource allocation in infection prevention and control. This information should be directed to those able to effect change in the health care setting’s practices. The dissemination of surveillance information should take place on a systematic, ongoing basis so that health care providers and administrators can anticipate the receipt of this information and use it the evaluation and planning of patient care practices.

All information provided in surveillance reports must be clear, easy to follow and provide only the information required. Information should be presented using a standardized format, as managers and/or health care providers often have little time available for an in-depth review of the data. Whenever possible, the Infection Control Team should employ visual aids, such as bar or pie charts, graphs and tables, in order to display surveillance data. Important trends, such as an increasing HAI rate, may be quickly identified when portrayed visually.

Refer to Appendix H for information regarding tools for the visual display of surveillance data.

---

**Recommended Practice #16:**

Communication of surveillance data should take place on an ongoing, systematic basis and be targeted to those with the ability to change infection control practice. All surveillance reports should be clear and easy to follow, including the use of visual aids including pie charts, bar charts and graphs.

---

**3. Communication of Special Alerts and Outbreaks**

Timely communication of alerts to health care providers following identification of an emerging risk of infection is important. For example, if the Infection Control Team detects a sharp increase in the rate of infections caused by MRSA in a particular patient/resident care area of their facility, they may issue a facility-wide alert documenting the increase. The alert may also serve as an opportunity to remind patient/resident care staff of infection prevention and control practices, such as hand hygiene and routine MRSA screening practices for patients/residents admitted to that ward. Any additional infection prevention and control precautions instituted in response to this increase in HAI rate may also be outlined in this alert.

If a reportable communicable disease is identified, the local public health unit shall be notified.

As with surveillance reports, alerts should present only key information with the use of graphs or charts whenever possible to communicate the main messages quickly and effectively.
Examples of how an Infection Control Team can undertake the dissemination of information generated through a surveillance system are provided in Boxes 18 and 19.

### Box 18: Communication and Use of Surveillance Information (acute care example)

- **At City General Hospital, the Infection Control Team collaborates closely with the ICU to investigate sources of nosocomial infections.**
- **The Infection Control Team forms a working group with the ICU manager and medical director to address the risk of nosocomial infection on an ongoing basis.**
- **This working group holds a quarterly workshop with the patient care staff to evaluate and review changes to patient care practices aimed at reducing the risk of infection.**
- **CVC-associated bloodstream infections (BSI) are a major concern for the ICU working group. In preparation for this workshop, the Infection Control Team puts together a report documenting the risk of CVC-associated BSI among patients treated in the ICU over the past year.**
- **The graph below shows the BSI rate per 1000 CVC days:**

![Graph showing Central line associated bloodstream infections](image)

- **The ICPs from City General Hospital dialogue with other member hospitals of the Regional Infection Control Network and the Community and Hospital Infection Control Association (CHICA) - Canada.**
- **They find that City General Hospital’s rates of CVC-associated BSI are 3% higher than other similar hospitals serving similar patient populations; rates of these infections in other hospitals average 5 per 1000 line days.**
- **The ICU working group is in agreement that improvements to patient care practices have the potential to decrease the risk of BSI.**
- **They find that City General Hospital uses similar approaches in surveillance and has a similar ICU case mix to other hospitals, and that differences in these factors are not likely to explain the difference in rates.**
- **Together, the ICP and ICU undertake steps to increase compliance with guidelines for the insertion and change of CVCs. The ICPs embark on an education initiative among patient care staff to raise awareness of the guidelines for CVC insertion (e.g., that it take place under maximum barrier precautions) and for frequency of CVC changes. The ICU manager and medical director work to ensure that all necessary supplies are available for maximum barrier precautions for insertion and implement a reminder system for central line change.**
The following key features help to ensure that surveillance graphs are easy to interpret:

1. The graph has a clear title with date and a subtitle that summarizes the data being presented.
2. Both axes are labelled, with time on the x (horizontal) axis as per customary practice.
3. The denominator is clearly indicated (per 1000 central line days).
4. The timeframe of interest is clearly indicated (current and past quarterly surveillance periods).
5. There is a legend to accompany the data shown in the graph (on the right hand side in the above legend).

Unlabelled or improperly labelled axes and graphs without legends are common pitfalls impeding communication made by those presenting data that are easily rectified.

---

**Box 19: Communication and Use of Surveillance Information (long-term care example)**

**Urinary Tract Infections**

The ICP at Forest Manor follows potential cases of UTI as reported from the ward staff and finds an increase in the number of symptomatic UTIs associated with indwelling urinary catheters. Following collection of data on the population at risk, the ICP finds that the rate of UTIs per 1000 catheter days has not increased from previous periods. The number of resident catheter days has, however, increased from previous periods.

The ICP reasons that the increased number of UTIs is due to an increase in the exposure to indwelling catheters.

The ICP shares this information with nursing and administrative staff at the monthly staff meeting and initiates discussions on potential reasons for the increase in indwelling urinary catheter use and on ways that the use of these devices can possibly be decreased.

**Acute Respiratory Infections**

The ICP at Forest Manor also compiles data on the rates of lower respiratory tract infections in residents over the past five previous influenza seasons.

The ICP presents this data alongside the proportion of patient care staff receiving annual influenza vaccination, as documented in employee records, in the graphs below.

The graphs demonstrate a substantial decline in the rates of respiratory tract infection over the last two influenza seasons at Forest Manor, coinciding with the highest rates of vaccine uptake among health care providers.

At Forest Manor, the proportion of immunized health care providers increased modestly from 2001 to 2003 following an active education campaign to increase compliance with vaccine recommendations.

It was only in 2005, when vaccination coverage was at its highest, that the most substantial impact on lowering the rates of lower respiratory tract infections was achieved.
These data clearly demonstrated the impact that health care provider immunization had on respiratory tract infections in residents, and they were used to form the institutional policies necessary to achieve vaccine coverage in staff.
EVALUATE THE SURVEILLANCE SYSTEM

A final recommended practice is evaluation of the surveillance system, which entails a review of:

- how efficiently and effectively the surveillance system works (process evaluation); and
- how the information produced by a surveillance system is used to reduce the risk of health care-associated infection (outcome evaluation).

1. Process Evaluation

A surveillance system should have built-in procedures for the evaluation of how the system is working on a day-to-day basis. Periodic review of surveillance methods should be incorporated as part of regular Infection Control Committee meetings. These review sessions will provide an opportunity for the Infection Control Team to challenge case definitions, case finding methods (including number of potential cases missed) and other surveillance procedures. The participation of internal/external peers, such as Infection Control Professionals from other health care settings, at these sessions can provide a helpful perspective and new ideas and suggestions as to how a facility's surveillance system may be improved.

An example of a peer review session to evaluate surveillance definitions may be found in Box 20.

<table>
<thead>
<tr>
<th>Box 20: Surveillance Process Evaluation (acute care example)</th>
</tr>
</thead>
<tbody>
<tr>
<td>➢ The Infection Control Team at City General Hospital invites ICPs from nearby member hospitals within the Regional Infection Control Networks and an epidemiologist from the local public health unit to join them in an exercise that will assess the consistency of application of case definitions for infection.</td>
</tr>
<tr>
<td>➢ A series of charts from patients with suspected or confirmed health care-associated infections are selected at random and all participants at the review apply case definitions, deciding whether a particular case meets the definition for infection based on all available chart information.</td>
</tr>
<tr>
<td>➢ The group discusses and challenges each others’ application of case definitions and comes to consensus on certain issues.</td>
</tr>
<tr>
<td>➢ This exercise assists in assuring consistency in application of case definitions both within City General Hospital and in other institutions in the region.</td>
</tr>
</tbody>
</table>

2. Outcome Evaluation

The Infection Control Team may use the following questions to evaluate how the surveillance system is impacting infection prevention and control and how the information produced from surveillance is used to reduce HAIs in their health care setting:

- Did the surveillance system detect clusters or outbreaks?
- Which patient/resident care practices were changed based on surveillance data?
- Were the data used to assess the efficacy of interventions?
- Were the data used to make procedural changes to decrease the endemic rate of infection?
- Is surveillance of this infection still of value (if the number of cases or rate of infection is exceptionally low, then surveillance for the infection may not be warranted)?

Where surveillance data are not used as effectively as they could be to effect changes to practice, the Infection Control Team should examine the underlying reasons for this and if necessary make changes to its surveillance system.

3. **Ongoing Surveillance System Improvement**

It should be expected that a surveillance system will undergo continual modification or re-alignment to ensure that it is working towards improved infection prevention and control, as demonstrated in Figure 1 by the continuous feedback loop of the surveillance system components. Modifications to a surveillance system might include:

- re-assessment of the infections monitored;
- changes to the approach to case finding; and
- ways in which information generated by the system is communicated to other health care providers and decision-makers.

**Recommended Practice #17:**

Hospitals and long-term care homes should regularly review the surveillance process implemented in their facility (e.g., application of case definitions, case finding and communication methods) and make modifications as needed.

At least once annually, hospitals and long-term care homes should review the outcomes of their surveillance systems (i.e., reductions to the risk of infection) and re-align system objectives as required.
## Summary of Best Practices

This summary table is intended to assist with self-assessment internal to the health care setting for quality improvement purposes. See complete text for rationale.

<td></td>
<td></td>
<td></td>
<td></td>
<td></td>
</tr>
</tbody>
</table>

### 1.0

As a first step in the planning of a surveillance system, it is a recommended practice that a health care setting assess:

- the types of patients/residents that it serves;
- the key medical interventions and procedures that they undergo;
- the types of infections for which they are most at risk.

This assessment is done to establish priorities for the surveillance system.

### 2.0

Syndromic surveillance of respiratory infections and gastroenteritis should be undertaken in all hospitals and long-term care homes. Where hospitals and long-term care homes select outcomes for surveillance in addition to the infections listed above, the following should be considered:

- the frequency of the infection;
- the impacts of the infection (including percent case fatality and excess costs associated with the infection); and
- the preventability of the infection.

In both hospitals and long-term care homes, the outcomes selected for surveillance should be re-evaluated at least annually.

Appendices

Appendix A: Evidence for the Effectiveness of Surveillance Systems in Reducing Health Care-Associated Infections

A search strategy was developed and executed in MEDLINE (1950-2007) to identify all English language studies that investigated whether the establishment of a surveillance system was associated with a decrease in the rate of health care-associated infections (HAIs). Combinations of the search terms indicated below initially yielded 317 studies. Subsequent review of the abstracts from the electronic records and of reference lists identified 11 studies that examined a change in the rate of HAIs following establishment of a surveillance system in a hospital or long-term care home.

Search Terms Used to Identify Studies for Subsequent Review

- Nosocomial infection.mp. or cross-infection
- Long-term care
- Health-care acquired
- Sentinel surveillance/ or population surveillance
- Surgical wound Infection/ or surgical site infection.mp. / or surveillance.mp
- Urinary tract infections
- Pneumonia/ or ventilator-associated
- Drug resistance, Multiple/ or Drug Resistance, Microbial
- Catheterization, central venous
- Evaluation studies
- Effectiveness
- Cost benefit analysis
- Benchmarking
- Practice guidelines/ or best practices

The studies that were identified were then assessed with respect to two main evaluative criteria:

1. **Adjustment for case mix factors.** Studies were assessed by whether they controlled for potential differences in the risk of HAIs that could have explained any changes in HAI rates prior to, and following, the establishment of surveillance systems.

2. **Identifiable impact of the surveillance system.** An examination of the mechanisms through which reductions in HAI rates are likely to have resulted are important to the assessment of the contribution of the surveillance system (and/or the changes it brings about) to reduced rates of HAI.

Eleven studies were identified that examined the impact of surveillance on risk of HAI. The design, populations examined, results and evaluation of each of the 11 studies are summarized in the table below.
Although none of the studies completely met the evaluative criteria, overall this review shows a clear association between development of a system of surveillance and reduction in the risk of HAIs in hospitals. Although none of the studies examined the impact of surveillance systems in long-term care, there is no reason to suggest that similar effects would not be observed in that setting.
## Summary of Studies Associating Change in Risk of Nosocomial Infection with Establishment of a Surveillance System

Appendix B: Recommended Case Definitions for Surveillance of Health Care-Associated Infections in Hospitals

A. PRIMARY BLOODSTREAM INFECTION

Primary bloodstream infections are classified according to the criteria used, either as laboratory-confirmed bloodstream infection (LCBI) or clinical sepsis (CSEP).

CSEP may be used to report only a primary BSI in neonates (<30 days old) and infants (≤1 year old).

I. Laboratory-confirmed Bloodstream Infection (LCBI)

LCBI criteria may be used for all patients. LCBI must meet one of the following three criteria:

**Criterion 1:** Patient has a recognized pathogen cultured from one or more blood cultures;

\textbf{and} organism cultured from blood is not related to an infection at another site.

**Criterion 2:** Patient has at least one of the following signs or symptoms: fever (>38°C), chills, or hypotension;

\textbf{and} signs and symptoms and positive laboratory results are not related to an infection at another site;

\textbf{and} at least one of the following:

a) common skin contaminant (i.e., diphtheroids [Corynebacterium spp.], Bacillus spp., Propionibacterium spp., coagulase-negative staphylococci, viridans group streptococci, Aerococcus spp., Micrococcus spp.) is cultured from two or more blood cultures drawn on separate occasions;

b) common skin contaminant (i.e., diphtheroids [Corynebacterium spp.], Bacillus spp., Propionibacterium spp., coagulase-negative staphylococci, viridans group streptococci, Aerococcus spp., Micrococcus spp.) is cultured from at least one blood culture from a patient with an intravascular line, and the physician institutes appropriate antimicrobial therapy; or

c) positive antigen test on blood (e.g., H. influenzae, S. pneumoniae, N. meningitidis, or Group B Streptococcus).

**Criterion 3:** Patient ≤1 year of age has at least one of the following signs or symptoms: fever (>38°C, rectal), hypothermia (<37°C, rectal), apnea, or bradycardia;

\textbf{and} signs and symptoms and positive laboratory results are not related to an infection at another site;

\textbf{and}
at least one of the following:

a) common skin contaminant (i.e., diphtheroids [Corynebacterium spp.], Bacillus spp., Propionibacterium spp., coagulase-negative staphylococci, viridans group streptococci, Aerococcus spp., Micrococcus spp.) is cultured from two or more blood cultures drawn on separate occasions; or

b) common skin contaminant (i.e., diphtheroids [Corynebacterium spp.], Bacillus spp., Propionibacterium spp., coagulase-negative staphylococci, viridans group streptococci, Aerococcus spp., Micrococcus spp.) is cultured from at least one blood culture from a patient with an intravascular line, and physician institutes appropriate antimicrobial therapy.

II. Clinical Sepsis (CSEP)

CSEP may be used only to report a primary BSI in neonates and infants.

**Criterion:**

Patient ≤ 1 year of age has at least one of the following clinical signs or symptoms with no other recognized cause: fever (>38°C, rectal), hypothermia (<37°C, rectal), apnoea, or bradycardia;

and

blood culture not done or no organisms or antigen detected in blood;

and

no apparent infection at another site;

and

physician institutes treatment for sepsis.

B. PNEUMONIA

Pneumonia (PNEU) is identified by using a combination of radiological, clinical and laboratory criteria. Physician’s diagnosis alone is not an acceptable criterion for nosocomial pneumonia.

Algorithms have been developed for three types of pneumonias:
### I. Site-Specific Algorithms for Clinically Defined Pneumonia (PNU1)

  NOTE: In patients without underlying pulmonary or cardiac disease (e.g., respiratory distress syndrome, bronchopulmonary dysplasia, pulmonary edema, or chronic obstructive pulmonary disease), one definitive chest radiograph is acceptable. | Patient who is immunocompromised has at least one of the following:  
  - Fever (>38°C) with no other recognized cause  
  - For adults ≥70 years old, altered mental status with no other recognized cause  
  - New onset of purulent sputum, or change in character of sputum, or increased respiratory secretions, or increased suctioning requirements  
  - New onset or worsening cough, or dyspnea, or tachypnea  
  - Rales or bronchial breath sounds  
  - Worsening gas exchange (e.g., $O_2$ desaturations (e.g., $PaO_2/FiO_2$ ≤ 240), increased oxygen requirements, or increased ventilator demand)  
  - Haemoptysis  
  - Pleuritic chest pain | At least one of the following:  
  - Matching positive blood and sputum cultures with *Candida* spp.  
  - Evidence of fungi or *Pneumocystis carinii* from minimally contaminated LRT specimen (e.g., BAL or protected specimen brushing) from one of the following:  
    - Direct microscopic exam  
    - Positive culture of fungi  
  - Positive growth in blood culture not related to another source of infection  
  - Positive growth in culture of pleural fluid  
  - Positive quantitative culture from minimally contaminated LRT specimen (e.g., BAL or protected specimen brushing)  
  - ≥ 5% BAL-obtained cells contain intracellular bacteria on direct microscopic exam (e.g., Gram stain)  
  - Histopathologic exam shows at least one of the following evidences of pneumonia:  
    - Abscess formation or foci of consolidation with intense PMN accumulation in bronchioles and alveoli  
    - Positive quantitative culture of lung parenchyma. Evidence of lung parenchyma invasion by fungal hyphae or pseudohyphae |
C. URINARY TRACT INFECTIONS

Catheter-associated urinary tract infections are classified into two groups with specific sets of criteria for each: symptomatic urinary tract infections (SUTI) and asymptomatic bacteriuria (ASB).

I. Symptomatic Urinary Tract Infection (SUTI)

A symptomatic urinary tract infection must meet at least one of the following criteria:

Criterion 1: Patient has at least one of the following signs or symptoms with no other recognized cause: fever (>38°C), urgency, frequency, dysuria, or suprapubic tenderness;

and

patient has a positive urine culture, that is, ≥10^5 microorganisms per mL of urine with no more than two species of microorganisms.

Criterion 2: Patient has at least two of the following signs or symptoms with no other recognized cause: fever (>38°C), urgency, frequency, dysuria, or suprapubic tenderness;

and

at least one of the following:

a) positive dipstick for leukocyte esterase and/or nitrate;

b) pyuria (urine specimen with ≥10^6/mL or ≥3/high power field of unspun urine);

c) organisms seen on Gram stain of unspun urine;

d) at least two urine cultures with repeated isolation of the same uropathogen (Gram-negative bacteria or S. saprophyticus) with ≥10^2 colonies/mL in nonvoided specimens;

e) ≤10^5 colonies/mL of a single uropathogen (gram-negative bacteria or S. saprophyticus) in a patient being treated with an effective antimicrobial agent for a urinary tract infection;

f) physician diagnosis of a urinary tract infection;

g) physician institutes appropriate therapy for a urinary tract infection.

Criterion 3: Patient ≤ 1 year of age has at least one of the following signs or symptoms with no other recognized cause: fever (>38°C rectal), hypothermia (<37°C rectal), apnoea, bradycardia, dysuria, lethargy, or vomiting;

and

patient has a positive urine culture, that is, ≥10^5 microorganisms per mL of urine with no more than two species of microorganisms.

Criterion 4: Patient ≤ 1 year of age has at least one of the following signs or symptoms with no other recognized cause: fever (>38°C rectal), hypothermia (<37°C rectal), apnoea, bradycardia, dysuria, lethargy, or vomiting;

and

at least one of the following:

a) positive dipstick for leukocyte esterase and/or nitrate;
b) pyuria (urine specimen with $\geq10$ WBC/mL or $\geq3$ WBC/high power field of unspun urine);
c) organisms seen on Gram stain of unspun urine;
d) at least two urine cultures with repeated isolation of the same uropathogen (Gram-negative bacteria or $S.$ saprophyticus) with $\geq10^2$ colonies/mL in nonvoided specimens;
e) $\leq10^5$ colonies/mL of a single uropathogen (Gram-negative bacteria or $S.$ saprophyticus) in a patient being treated with an effective antimicrobial agent for a urinary tract infection;
f) physician diagnosis of a urinary tract infection;
g) physician institutes appropriate therapy for a urinary tract infection.

II. Asymptomatic Bacteriuria (ASB)
An asymptomatic bacteriuria must meet at least one of the following criteria:

**Criterion 1:** Patient has had an indwelling urinary catheter within 7 days before the culture;

*and*

patient has a positive urine culture, that is, $\geq10^5$ microorganisms per mL of urine with no more than two species of microorganisms;

*and*

patient has no fever (>38°C), urgency, frequency, dysuria, or suprapubic tenderness.

D. SURGICAL SITE INFECTIONS
Surgical site infections are categorized into three groups:

I. Superficial Incisional SSI
Criterion: Infection occurs within 30 days after the operative procedure;

*and*

involves only skin and subcutaneous tissue of the incision;

*and*

patient has at least one of the following:

a) purulent drainage from the superficial incision;
b) organisms isolated from an aseptically obtained culture of fluid or tissue from the superficial incision;
c) at least one of the following signs or symptoms of infection:
   i. pain or tenderness, localized swelling, redness, or heat; and
   ii. superficial incision is deliberately opened by surgeon, and is culture-positive or not cultured. A culture-negative finding does not meet this criterion;
d) diagnosis of superficial incisional SSI by the surgeon or attending physician.

Reporting Instructions:

1. Do not report a stitch abscess (minimal inflammation and discharge confined to the points of suture penetration) as an infection.
2. Do not report a localized stab wound infection as SSI, instead report as skin or soft tissue infection, depending on its depth.
3. Report infection of the circumcision site in newborns as SSTCIRC. Circumcision is not an NHSN operative procedure.
4. Report infection of the episiotomy site as REPR-EPIS. Episiotomy is not an NHSN operative procedure.
5. Report infected burn wound as SST-BURN.
6. If the incisional site infection involves or extends into the fascial and muscle layers, report as a deep incisional SSI.
7. Classify infection that involves both superficial and deep incision sites as deep incisional SSI.

II. Deep Incisional SSI

Criterion: Infection occurs within 30 days after the operative procedure if no implant is left in place or within 1 year if implant is in place and the infection appears to be related to the operative procedure;

and

involves deep soft tissues (e.g., fascial and muscle layers) of the incision;

and

patient has at least one of the following:

a) purulent drainage from the deep incision but not from the organ/space component of the surgical site
b) a deep incision spontaneously dehisces or is deliberately opened by a surgeon when the patient has at least one of the following signs or symptoms:
   i. fever (> 38°C), or
   ii. localized pain or tenderness, unless incision is culture-negative

   c) an abscess or other evidence of infection involving the deep incision is found on direct examination, during reoperation or by histopathologic or radiologic examination

   d) diagnosis of a deep incisional SSI by a surgeon or attending physician

Reporting Instructions:

Classify infection that involves both superficial and deep incision sites as deep incisional SSI.
III. Organ/Space SSI

An organ/space SSI involves any part of the body, excluding the skin incision, fascia, or muscle layers, that is opened or manipulated during the operative procedure. Specific sites are assigned to organ/space SSI to further identify the location of the infection. The table below lists the specific sites that must be used to differentiate organ/space SSI. An example is appendectomy with subsequent subdiaphragmatic abscess, which would be reported as an organ/space SSI at the intra-abdominal specific site (SSI-IAB).

**Criterion:** Infection occurs within 30 days after the operative procedure if no implant is left in place or within one year if implant is in place and the infection appears to be related to the operative procedure;

*and*

infection involves any part of the body, excluding the skin incision, fascia, or muscle layers, that is opened or manipulated during the operative procedure;

*and*

patient has at least one of the following:

- a) purulent drainage from a drain that is placed through a stab wound into the organ/space;
- b) organisms isolated from an aseptically obtained culture of fluid or tissue in the organ/space;
- c) an abscess or other evidence of infection involving the organ/space that is found on direct examination, during reoperation, or by histopathologic or radiologic examination;
- d) diagnosis of an organ/space SSI by a surgeon or attending physician.

**Reporting Instructions:**

1. Occasionally, an organ/space infection drains through the incision. Such infection generally does not involve re-operation and is considered a complication of the incision. Therefore, it is classified as a deep incisonal SSI.
2. Report culture specimen from organ/space as DD (deep drainage).

Appendix C: Recommended Case Definitions for Surveillance of Health Care-Associated Infections in Long-term Care Homes

A. RESPIRATORY TRACT INFECTION

I. Common Cold Syndromes/Pharyngitis
The resident must have at least two of the following signs or symptoms:
   a) runny nose or sneezing;
   b) stuffy nose (i.e., congestion);
   c) sore throat or hoarseness or difficulty in swallowing;
   d) dry cough;
   e) swollen or tender glands in the neck (cervical lymphadenopathy).

Comment: Fever may or may not be present. Symptoms must be new, and care must be taken to ensure that they are not caused by allergies.

II. Influenza-like Illness (ILI)
Both of the following criteria must be met:
1. Fever (≥38°C)*
   and
2. The resident must have at least three of the following signs or symptoms:
   a) chills;
   b) new headache or eye pain;
   c) myalgias;
   d) malaise or loss of appetite;
   e) sore throat;
   f) new or increased dry cough.

*A single temperature of 38°C, taken at any site.

Comment: This diagnosis can be made only during influenza season (November to April in Canada). If criteria for influenza-like illness and another upper or lower respiratory tract infection are met at the same time, only the diagnosis of influenza-like illness should be recorded.

III. Pneumonia
Both of the following criteria must be met:
1. Interpretation of a chest radiograph as demonstrating pneumonia, probable pneumonia, or the presence of an infiltrate. If a previous radiograph exists for comparison, the infiltrate should be new.
and

2. The resident must have at least two of the signs and symptoms described under “other lower respiratory tract infections.”

Comment: Non-infectious causes of symptoms must be ruled out. In particular, congestive heart failure may produce symptoms and signs similar to those of respiratory infections.

IV. Other Lower Respiratory Tract Infection (bronchitis, tracheobronchitis)
The resident must have at least three of the following signs or symptoms:

   a) new or increased cough;
   b) new or increased sputum production;
   c) fever (≥38° C);
   d) pleuritic chest pain;
   e) new or increased physical findings on chest examination (rales, rhonchi, wheezes, bronchial breathing);
   f) one of the following indications of change in status or breathing difficulty:
      i. new/increased shortness of breath or respiratory rate ≥ 25 per minute; or
      ii. worsening mental or functional status.*

* Significant deterioration in the resident’s ability to carry out the activities of daily living or in the resident’s cognitive status, respectively.

Comment: This diagnosis can be made only if no chest film was obtained or if a radiograph failed to confirm the presence of pneumonia.

B. URINARY TRACT INFECTION

Urinary tract infection includes only symptomatic urinary tract infections. Surveillance for asymptomatic bacteriuria (defined as the presence of a positive urine culture in the absence of new signs and symptoms of urinary tract infection) is not recommended, as this represents baseline status for many residents.

Symptomatic Urinary Tract Infection

One of the following criteria must be met:

1. The resident does not have an indwelling urinary catheter and has at least three of the following signs and symptoms:

   a) fever (≥38° C) or chills;
   b) new or increased burning pain on urination, frequency or urgency;
   c) new flank or suprapubic pain or tenderness;
   d) change in character of urine;†
   e) worsening of mental or functional status (may be new or increased incontinence).
2. The resident has an indwelling catheter and has at least two of the following signs or symptoms:

   a) fever ($\geq 38^\circ C$) or chills;
   b) new flank or suprapubic pain or tenderness;
   c) change in character of urine;†
   d) worsening of mental or functional status.

† Change in character may be clinical (e.g., new bloody urine, foul smell, or amount of sediment) or as reported by the laboratory (new pyuria or microscopic haematuria). For laboratory changes, this means that a previous urinalysis must have been negative.

Comment: It should be noted that urine culture results are not included in the criteria. However, if an appropriately collected and processed urine specimen was sent and if the resident was not taking antibiotics at the time, then the culture must be reported as either positive or contaminated.

Because the most common occult infectious source of fever in catheterized residents is the urinary tract, the combination of fever and worsening mental or functional status in such residents meets the criteria for a urinary tract infection. However, particular care should be taken to rule out other causes of these symptoms. If a catheterized resident with only fever and worsening mental or functional status meets the criteria for infection at a site other than the urinary tract, only the diagnosis of infection at this other site should be made.

C. EYE, EAR, NOSE, AND MOUTH INFECTION

I. Conjunctivitis

One of the following criteria must be met:

1. Pus appearing from one or both eyes, present for at least 24 hours;

or

2. New or increased conjunctival redness, with or without itching or pain, present for at least 24 hours (also known as “pink eye”).

Comment: Symptoms must not be due to allergy or trauma to the conjunctiva.

II. Ear Infection

One of the following criteria must be met:

1. Diagnosis by a physician* of any ear infection;

or

2. New drainage from one or both ears (non-purulent drainage must be accompanied by additional symptoms, such as ear pain or redness).

* Requires a written note or a verbal report from a physician specifying the diagnosis. Usually implies direct assessment of the resident by a physician. An antibiotic order alone does not fulfill this
criterion. In some homes, it may be appropriate also to accept a diagnosis made by other qualified clinicians (e.g., nurse practitioner, physician associate).

III. Mouth and Perioral Infection
Oral and perioral infections, including oral candidiasis, must be diagnosed by a physician or a dentist.

IV. Sinusitis
The diagnosis of sinusitis must be made by a physician.

D. SKIN INFECTION

I. Cellulitis/Soft Tissue/Wound Infection
One of the following criteria must be met:

1. Pus present at a wound, skin, or soft tissue site;

or

2. The resident must have four or more of the following signs or symptoms:
   a) fever (≥38° C) or worsening mental/functional status;
   b) heat,
   c) redness,
   d) swelling,
   e) tenderness or pain,
   f) serous drainage.

II. Fungal skin infection
The resident must have both:

1. a maculopapular rash;

and

2. either physician diagnosis or laboratory confirmation.†

† For Candida or other yeast, laboratory confirmation includes positive smear for yeast or culture for Candida spp.; for herpetic infections, positive electron microscopy or culture of scraping or swab; for scabies, positive microscopic examination of scrapings.
III. Herpes simplex and Herpes zoster Infection.
For a diagnosis of cold sores or shingles, the resident must have both:

a) a vesicular rash;

and

b) either physician diagnosis or laboratory confirmation.

IV. Scabies
The resident must have both:

1. a maculopapular and/or itching rash; and

2. either physician diagnosis or laboratory confirmation.

Comment: Care must be taken to ensure that a rash is not allergic or secondary to skin irritation.

E. GASTROINTESTINAL TRACT INFECTION

Gastroenteritis
One of the following criteria must be met:

1. Two or more loose or watery stools above what is normal for the resident within a 24-hour period;

2. Two or more episodes of vomiting in a 24-hour period;

3. Both of the following:
   a) a stool culture positive for a pathogen (Salmonella, Shigella, E. coli O157:H7, Campylobacter) or a toxin assay positive for C. difficile toxin; and
   b) at least one symptom or sign compatible with gastrointestinal tract infection (nausea, vomiting, abdominal pain or tenderness, diarrhea).

Comment: Care must be taken to rule out non-infectious causes of symptoms. For instance, new medications may cause both diarrhea and vomiting; vomiting may be associated with gallbladder disease.

F. SYSTEMIC INFECTION

I. Primary Bloodstream Infection
One of the following criteria must be met:

1. Two or more blood cultures positive for the same organism;

2. A single blood culture documented with an organism thought not to be a contaminant and at least one of the following:
a) fever (≥38° C);
b) new hypothermia (<34.5° C, or does not register on the thermometer being used);
c) a drop in systolic blood pressure of .30 mm Hg from baseline;
d) worsening mental or functional status.

Comment: Bloodstream infections related to infection at another site are reported as secondary bloodstream infections and are not included as separate infections.

II. Unexplained Febrile Episode

The resident must have documentation in the medical record of fever (≥38° C) on two or more occasions at least 12 hours apart in any 3-day period, with no known infectious or non-infectious cause.

Appendix D: Sample Sentinel Surveillance Sheet

(To be completed by ward/unit staff each day)

Daily Surveillance Tool for FRI and Enteric Infections in Acute Care Patient Units

Date: ___________________ Patient Unit: _______________ Page ____ of _____

- Each shift is to update this form.
- Any new onset of symptoms of fever, cough, and shortness of breath, vomiting, diarrhea and/or pneumonia in patients must be reported to the attending physician immediately and a message for Infection Prevention & Control must be left.

Appendix E: Summary Sheet for Calculation of Infection Surveillance Rates

1. Incidence Density Rates (adjusts for patient/resident length of stay)
   
   **Example infections:**
   - AROs (infections and/or colonizations)
   - Respiratory infections
   - Skin and soft tissue infections

   Number of cases over specified time period (e.g. surveillance quarter) \( \times \) 10,000
   Total number patient/resident days in hospital or facility over time period

2. Device-Associated Infection Rates
   
   **Example infections**
   - Central line-associated bloodstream infections
   - Ventilator-associated pneumonias
   - Indwelling catheter-associated urinary tract infections

   Number of cases over specified time period (e.g. surveillance quarter) \( \times \) 1000
   Total number days that patients/residents were exposed to the device

3. Surgical Site Infection Rates (SSIs)
   
   Number of cases over specified time period following specific operative procedure \( \times \) 100
   Total number days that patients/residents underwent the same operative procedure in the same time period

   **Stratification of SSI rates by wound class**
   
   **For Wound Classes I-II only:**
   Number of cases over specified time period following specific operative procedure \( \times \) 100
   Total number days that patients/residents underwent the same operative procedure in the same time period

   **For Wound Classes III-IV only:**
   Number of cases over specified time period following specific operative procedure \( \times \) 100
   Total number days that patients/residents underwent the same operative procedure in the same time period

### Appendix G: Classification of Surgical Procedures According to Wound Class Risk

<table>
<thead>
<tr>
<th>Wound class</th>
<th>Definition</th>
<th>Examples</th>
<th>Risk of Surgical Site Infection</th>
</tr>
</thead>
<tbody>
<tr>
<td>Dirty surgery</td>
<td>- Clinically infected operative wound or perforated viscera or old, traumatic wound with retained devitalized tissue, purulent draining</td>
<td>- Repair of an open fracture that occurred three days earlier</td>
<td>HIGH RISK</td>
</tr>
</tbody>
</table>
| Contaminated surgery   | - Acute, nonpurulent, inflamed operative wound or open fresh, accidental wound  
- An operative procedure with major breaks in sterile technique or gross spillage; macroscopic soiling of the operative field | - Appendectomy for appendicitis  
- Biliary or genitourinary tract surgery with infected bile or urine |                                  |
| Clean-contaminated      | - Uninfected operative wound where the respiratory, alimentary, genital, or uninfected urinary tracts are entered | - Laryngectomy  
- Elective colorectal surgery  
- Uncomplicated appendectomy  
- Cholecystectomy  
- Transurethral resection of prostate gland |                                  |
| surgery                 |                                                                           |                                                                          |                                  |
| Clean surgery           | - Uninfected, uninfamed operative wound where mucosa of the respiratory, alimentary, genitourinary tract or oropharyngeal cavity are not transversed (i.e., involves only sterile body sites)  
- Insertion of prosthesis or artificial device | - Herniorraphy  
- Mastectomy  
- Cosmetic surgery  
- Knee/hip replacement, heart valve | LOW RISK                      |

Appendix H: Tools for the Display of Surveillance Data

General guidelines for the presentation of data in graph or chart form are as follows:

1. There should be a title (and sub-title, if necessary) that clearly outlines the data being presented.
2. For graphs and bar charts, the rate of infection is usually presented on the Y (or vertical) axis and the units of the scale should be constant (i.e., the scale units should not increase halfway up the axis).
3. The denominator should be clearly indicated (e.g., per 1000 resident days, per 1000 central line days).
4. Time is usually presented on the X (or horizontal) axis.
5. Graphs and charts should include a legend.
6. The use of colour often adds to a graph but coloured graphs should not lose their meaning when printed in black and white (e.g., for those printing surveillance reports on a black and white office printer).
7. The timeframe for the surveillance period should be clearly indicated on the graph (e.g., Surveillance Q1 (Jan-March 2006), Influenza season (Nov-Apr. 2007).
8. In some cases it may be useful to have a data table below the graph so that the reader can check the exact value.

The figures below provide examples of the visual display of surveillance data. Additional examples are provided in the document, Boxes 18 and 19.

Pie chart of data on nosocomial infection in a long-term care home

![Relative frequencies of nosocomial infections in Long Term Care Facility B, 2006 (% of total infections)](image-url)
Bar graph displaying rates of procedure-specific surgical site infections with accompanying data table:

**Surgical site infections following Caesarian delivery:**
Hospital A relative to peer group of hospitals, Dec 2005-June 2006

<table>
<thead>
<tr>
<th>Rate of infection following Caesarean delivery in Hospital A per 100 Caesarean deliveries</th>
</tr>
</thead>
<tbody>
<tr>
<td>Dec</td>
</tr>
<tr>
<td>2.5</td>
</tr>
</tbody>
</table>

Mean rate of infection in comparison group of hospitals in the same region per 100 Caesarean deliveries

| Dec | Jan | Feb | Mar | Apr | May | Jun |
|---|
| 1.8 | 1.3 | 1.8 | 2.1 | 1.5 | 1.7 | 1.6 |
